Preface to Second Edition

Eight years have now passed since the first edition of this Encyclopedia. During that time the field has continued to grow – almost exponentially in some areas! In doing this second edition of the Encyclopedia, we are mindful of the growth as well as some of the advantages for updating entries and including new ones in this much used reference work. It has been gratifying to see this resource being heavily used with around 400,000 downloads since it first appeared!

In this second edition we have added nearly 400 new entries and updates on over 450 previous entries reflecting activity in the field since the first edition.

As with the first edition we have attempted to be comprehensive in scope with entries on a range of topics including not only research issues but biographies of important contributors to the field, legal and social policy issues, educational, behavioral, and medical interventions, treatments, and advances in basic sciences of behavior, communication, neurobiology, genetics, epidemiology, and so forth. For this edition, we have also included a new set of entries on countries giving brief overviews of the history of autism work and the current state of the field in both developed and developing countries. This latter group of entries also reflects the growing interest in autism around the world specifically in developing countries where infrastructure for both service, teaching, and research has become increasingly important. With the addition of our new entries, we have reached nearly 1800 entries in total.

As with the first edition we hope that this work provides an invaluable resource for parents, students, educators, researchers, and professionals alike. Even though these volumes appear in hard copy, in this new second edition we continually update entries and add new ones as these are needed. For this addition, I particularly thank our supporters at Springer – Judy Jones, Tina Shelton, and Sindhu Ramachandran, at Yale my helpful assistants Lori Klein and Monica Mleczek, and at the Autism Center at Southern Connecticut State University my assistant Eileen Farmer. I also particularly thank my Associate Editor Dr. Michael Powers who has assumed an important leadership role in the production of this edition. All of us hope you find this unique resource a valuable and helpful one. We are delighted to welcome you to this second edition.

Fred R. Volkmar

Preface to First Edition

Why an encyclopedia of autism? There are several answers to this question. They include the need to provide a comprehensive and current guide to the diverse knowledge now available. There has been a significant upsurge in research in autism during the past two decades. Several hundred papers were published in 1991 compared to more than 2,000 articles during 2011. The quantity of research (not even counting non-peer-reviewed publications) has increased so dramatically that it is difficult, if not impossible, for researchers and clinicians to keep up. Access to a reference work that provides an introduction to relevant information is clearly needed.

Although several excellent handbooks and textbooks have been published in recent years, these are, almost intrinsically, fated to become increasingly out of date more and more quickly. Fortunately, many of the same technological advances that have been adapted for use with individuals with autism have uses for those of us who support them. The ability to produce both a print reference work as well as an online version with additional content was a major attraction for us in undertaking this project. It also can be updated easily and will have additional content. The electronic format also provides for an extensive cross-referencing system, which is designed to facilitate rapid searching and information retrieval.

With contributions on a range of topics from leaders in the field, this reference work breaks new ground as a resource. The Encyclopedia contains several thousand entries relevant to autism and related conditions, including new research findings; entries on development and behavior; assessment methods and instruments; treatments and educational interventions; biographies of leaders in the field; and information relevant to epidemiology, social policy, and treatment planning.

Both I and the associate editors of this work hope that you will benefit from using the encyclopedia and welcome your feedback. By the time the print publication of this work appears, the online edition will already have had entries added reflecting new knowledge in various areas. We hope that this resource enhances the work of clinicians and researchers alike.

About the Editor

Fred R. Volkmar is the Irving B. Harris Professor of Child Psychiatry, Pediatrics, and Psychology at the Yale Child Study Center, Yale University School of Medicine, and the Dorothy Goodwin Family Chair of Special Education at Southern Connecticut State University. An international authority on Asperger's disorder and autism, Dr. Volkmar was the primary author of the DSM-IV autism and pervasive developmental disorders section. He has authored several hundred scientific papers and has coedited numerous books, including *Asperger Syndrome, Healthcare for Children on the Autism Spectrum: A Guide to Medical, Nutritional, and Behavioral Issues*, and the recently released third edition of the *Handbook of Autism and Pervasive Developmental Disorders*. He serves as associate editor of the *Journal of Autism*, the *Journal of Child Psychology and Psychiatry*, and the *American Journal of Psychiatry*. He also serves as co-chairperson of the autism/MR committee of the American Academy of Child and Adolescent Psychiatry. Since 2007 he has served editor of the *Journal of Autism* and more recently of the *Encyclopedia of Autism*.

List of Field Editors

George M. Anderson Laboratory of Developmental Neurochemistry, Yale Child Study Center, New Haven, CT, USA

[CHRNA7 deletions](#)

Definition

15q13.3 microdeletion syndrome (OMIM 612001, DECIPHER coordinates: chr15: 30,901,306-32,445,407, hg19) is the result of heterozygous deletions at chromosome 15q13.3, ranging in size from ~350 kb to 3.9 Mb. These deletions are mediated by nonallelic homologous recombination (NAHR) between four low copy repeat (LCR) elements: breakpoints (BPs) 3, 4, and 5, as well as the D-CHRNA7-LCR. The most common of these deletions, spanning 1.5 Mb to 2 Mb are mediated by BPs 4 and 5 and encompass six genes: *FAN1*, *MTMR10*, *TRPM1*, *KLF13*, *OTUD7A*, and *CHRNA7*, as well as one microRNA: *hsa-miR-211*. Of these genes, *CHRNA7* and *OTUD7A* are the top candidate genes (Yin et al. 2018; Gillentine and Schaaf 2015).

The estimated frequency of the most common 15q13.3 microdeletions is 1 in 5525 live births (0.19%) and is estimated to be higher (0.29%) among individuals with intellectual disability and idiopathic generalized epilepsy (1%) (Gillentine et al. 2018). However, these deletions also exhibit incomplete penetrance, with about 20% of individuals not having any diagnosed phenotypes. This contributes to 15q13.3 microdeletions being *de novo* (15%) and inherited (85%). Of note, studies have found that a large proportion of 15q13.3 microdeletion probands are adopted; so, while having unknown inheritance, it is likely that these are inherited from affected parents (Ziats et al. 2016).

Individuals carrying 15q13.3 microdeletions have a wide range of phenotypes, including intellectual disability/developmental delay, seizures/epilepsy, autism spectrum disorder (ASD), and schizophrenia (Ziats et al. 2016). In general, probands with 15q13.3 microdeletion syndrome have height, weight, and fronto-occipital circumference within the normal range. Over half of 15q13.3 microdeletion probands exhibit cognitive deficits, with a study of 18 probands finding the average full-scale IQ to be 60 (Ziats et al. 2016; Gillentine and Schaaf 2015). The next most prevalent phenotype is seizures/epilepsy, affecting about one third of probands. Language or speech impairments are also common, affecting just under one third of probands. Other neuropsychiatric phenotypes include schizophrenia, ASD or autistic features, ADHD or attention difficulties, and mood disorders in less than 20% of probands each. Abnormal behaviors, including aggression, and impulsiveness have been observed in about a quarter of the cases. Dysmorphic features are present in about one third of probands, although there is not a consistent pattern of dysmorphia.

While deletions between ~1.5 Mb and ~2 Mb are the most common, but both larger and smaller deletions are reported with similar clinical phenotypes. Notably, homozygous deletions at 15q13.3 have been reported and are phenotypically more severe, with probands exhibiting neonatal encephalopathy. Additionally, the reciprocal microduplication is also pathogenic, with incomplete penetrance as well and a similar range of phenotypes, although typically less severe (Gillentine and Schaaf 2015).

Several hypotheses have been proposed to explain the variable expressivity observed among 15q13.3 microdeletion syndrome probands. These include additional copy number changes and/or single nucleotide variants contributing to phenotypes and epigenetic changes. However, the most prominent hypothesis is the effect of modifier genes, in particular the human-specific fusion gene *CHRFAM7A*, consisting exons 5 through 10 of *CHRNA7* and a sequence of unknown function, *FAM7A*. The fusion gene is copy variable and polymorphic among the

population. Functional studies have shown that increasing amounts of *CHRFAM7A* can contribute to *CHRNA7* dysfunction (Ihnatovych et al. 2019).

Currently, there is no consistent treatment for 15q13.3 microdeletion syndrome. *CHRNA7*, encoding for the $\alpha 7$ nicotinic acetylcholine receptor (nAChR), has been suggested as a candidate gene. Dysfunction of the $\alpha 7$ nAChR is supported molecularly, with a decrease of the receptor resulting in decreased calcium flux through the channel (Gillentine et al. 2017). Due to this, $\alpha 7$ agonists and positive allosteric modulators (PAMs) have been suggested as a possible treatment and assessed among a few individuals with mixed results. One individual carrying a 15q13.3 microdeletion who exhibited recurrent rage outbursts was treated with galantamine, a nAChR allosteric modulator and acetylcholinesterase inhibitor, with positive results, although such drugs are known to have severe side effects (Cubells et al. 2011). Individuals with schizophrenia or autism spectrum disorder have also been treated with nAChR agonists in small studies with positive, but limited results (Olincy et al. 2016). To date, no large clinical trials have been performed using such compounds.

- The importance of deletions and duplications at 16p11.2 in ASD was recognized simultaneously by three research groups (Kumar et al. 2008; Marshall et al. 2008; Weiss et al. 2008). These findings have since been replicated multiple times. 16p11.2 CNVs are found in about 1% of individuals with autism, compared with less than 0.1% of the population. CNVs in this region have also been associated with intellectual disability, developmental delay, schizophrenia (duplications only), and obesity (deletions only) (<http://www.ncbi.nlm.nih.gov/books/NBK11167/>).
- CNVs involving this interval are among the most well-established risk factors for ASD. They also highlight the complexity of the genetic contribution to these syndromes: the CNVs are neither necessary (ASD can occur without 16p11.2 CNVs) nor sufficient (ASD is not always present with the CNV) to cause ASD. Both deletions and duplications can contribute to risk, and these variations may either be de novo or transmitted within families. Moreover, in some families in which one affected child carries a 16p11.2, there may be other affected family members who do not.

The region contains multiple biologically plausible gene candidates for ASD (see list below). At this time, it is not known whether a single gene is responsible for the ASD phenotype or if a combination of genes within the region accounts for the risk.

The genes in the 16p11.2 region are ALDOA, ASPHD1, C16orf53, C16orf54, CDIPT, CORO1A, DOC2A, FAM57B, FLJ25404, GPD3, HIRIP3, INO80E, KCTD13, LOC100271831, LOC440356, MAPK3, MAZ, MVP, PPP4C, PRRT2, QPRT, SEZ6L2, SLC7A5P1, SPN, TAOK2, TBX6, TMEM219, and YPEL3.

16p11.2

Stephan Sanders
Child Study Center, Yale University, New Haven,
CT, USA

Definition

16p11.2 refers to a particular region on the short (p) arm of chromosome 16 that corresponds to an approximately 500 kilobase copy number variation (CNV) that is strongly associated with the risk for ASD. The region contains 28 genes and is flanked by segmental duplications (stretches of near-identical DNA). These are known to increase the likelihood of a process known as non-homologous allelic recombination, which can lead to gains or losses of the chromosomal segment flanked by these repeats.

²University of North Carolina, Chapel Hill, NC, USA

Definition

Section 504 is a regulation of the Rehabilitation Act of 1973 that extends civil rights to individuals

with disabilities. Enforced by the Office of Civil Rights (OCR) within the US Department of Health and Human Services, Section 504 states that “*No otherwise qualified individual with a disability in the United States . . . shall, solely by reason of her or his disability, be excluded from the participation in, be denied the benefits of, or be subjected to discrimination under any program or activity receiving Federal financial assistance. . .*” (29 U.S.C. § 794(a)). Section 504 applies to any organization receiving federal funding; thus, it has important implications for individuals with autism spectrum disorders (ASD) and their participation in various educational, recreational, community, and employment settings.

Historical Background

The Civil Rights Act of 1964 and its prohibition of discrimination based on race, color, or national origin was a catalyst for the development of Section 504 of the 1973 Rehabilitation Act. Senator Hubert Humphrey (D., Minnesota) led the work to add an amendment to the Rehabilitation Act of 1973 that would address the discrimination of individuals with disabilities who had not been included under the Civil Rights Act. Section 504 was the first piece of legislation that specifically addressed the civil rights of individuals with disabilities.

Implementation of Section 504 was wrought with challenges. Initial responsibility for writing implementation regulations was left to the US Department of Health, Education, and Welfare (HEW). Though drafts of the regulations were written as early as 1975 (Pfeiffer 2002), by 1977, the regulations had yet to be signed and implementation of Section 504 had stalled. In response, on April 5, 1977, the American Coalition of Citizens with Disabilities (ACCD) led demonstrations in HEW regional offices across the country. These demonstrations and other lobbying efforts led to the signing of the regulations on April 28, 1977. Delays in the creation of government-wide implementation slowed the process of issuing regulations within individual federal agencies (National Council on Disability

2003). Each department within the executive branch of the federal government now has its own regulations for implementing the provisions of Section 504 (Yell 2006).

As the first civil rights legislation for individuals with disabilities, Section 504 of the 1973 Rehabilitation Act paved the way for future legislation for individuals with disabilities, including the 1990 adoption of the Americans with Disabilities Act (ADA) and the Individuals with Disabilities Education Act (IDEA). Together, Section 504, ADA, and IDEA protect the rights and equal participation of individuals with disabilities in employment, in education, and in the community.

Current Knowledge

Qualification Under Section 504

Section 504 specifically states that to be protected under the law, an individual must be determined to (1) have a physical or mental impairment that substantially limits one or more major life activities, (2) have a record of such an impairment, or (3) be regarded as having such an impairment. Though no exhaustive list of specific “mental or physical impairments” covered by Section 504 exists, regulatory provision 34 C.F.R. 104.3(j)(2) (i) defines a physical or mental impairment as “any physiological disorder or condition, cosmetic disfigurement, or anatomical loss . . . or any mental or psychological disorder.” Major life activities, as defined by the Section 504 regulations at 34 C.F.R. 104.3(j)(2)(ii), include functions such as caring for one’s self, performing manual tasks, walking, seeing, hearing, speaking, breathing, learning, and working. It is important to note that this list is also not considered exhaustive, and thus other activities or functions not explicitly stated may be considered “major life activities” under Section 504.

Since autism is a brain-based disorder (Wass 2011), individuals with a diagnosis of ASD would “have record” of a “mental impairment” that could potentially qualify them for protection under Section 504. Qualification is determined based upon the influence of an individual’s autism on his or her ability to perform a “major life activity.”

The characteristics of autism manifest in social interactions, communicative exchanges, and through restricted or stereotyped patterns of behavior, interests, or activities (American Psychiatric Association 2000). Though to qualify for Section 504 each person on the autism spectrum must be evaluated on an individual basis, the disorder could potentially influence many “major life activities.”

Application of Section 504 in Education (From Preschool Through Postsecondary)

The provisions of Section 504 extend civil rights to individuals with disabilities to ensure access to activities and programs for which they “otherwise qualify” (29 U.S.C. § 794(a)). In other words, an individual meets program or employment criteria despite his or her disability. Applied to public education, this means that the individual with a disability is of public school age. Schools providing a public education must ensure that students with disabilities have equal opportunity to benefit from educational programs and facilities under Section 504 (Yell 2006).

A central component of Section 504 as it applies to public schools is the provision of a free appropriate public education (FAPE). FAPE, as defined by Section 504, requires that a student with a disability be provided with regular or special education and related aids and services that are designed to meet his or her individual educational needs. These provisions must meet the individual’s needs as adequately as the needs of students without disabilities are met. Examples relevant to learners with ASD include using visuals to supplement verbal instruction, providing tape recorders, modifying textbooks, using behavior support techniques such as reinforcement, adjusting class schedules, and increasing classroom organization/structure.

Section 504 also requires that all educational programs be accessible to all learners. This does not mean that schools are required to make every room or program accessible to all students but that all learners have equal access to programming. For example, a school may offer multiple sections of a biology lab in three different classrooms. If one of the lab classrooms is accessible and two are not, the school still meets the expectation

of Section 504 because the educational program is accessible to all students. It is not permissible, however, to create a scenario where a disproportionate number of students with disabilities are assigned to the same program or activity because of accessibility issues. Returning to the example of the biology lab, it would not be acceptable for the school to create one section of the lab in which students with disabilities were overrepresented.

This issue of disproportionality, or overrepresentation, is related to the FAPE provision within Section 504 that students with disabilities and students without disabilities should be placed in the same setting, to the maximum extent appropriate to meet the needs of the students with disabilities. In addition, students with disabilities may not be excluded from participating in any school activities, including extracurricular programs such as recreational sports or special interest clubs, in which students without disabilities would participate (US Department of Education, Office of Civil Rights 2010).

Section 504 also requires that students with disabilities access programs and services in “comparable facilities.” In the event that a student with a disability is educated in a separate facility from their peers, a district must ensure that the facility is comparable (i.e., in terms of space, location, size) to the district’s other facilities. Thus, Section 504 protects students with disabilities from the historical practice of establishing special education classrooms in areas not conducive to learning, such as storage rooms or partitioned areas (Yell 2006).

Eligibility Determination

Since Section 504 and IDEA both protect the rights of individuals with disabilities in public education settings (through age 21), there is often confusion about eligibility requirements. It is important to note that not all students with disabilities who qualify for an individualized plan under Section 504 will meet the requirements for special education under IDEA. However, all students protected by IDEA also qualify for protections under Section 504. One reason for this distinction is that under IDEA, a disability must have an adverse impact on a student’s learning

that requires special education and related services. If a student does not require specialized instruction as a result of their disability, then he or she would not meet the requirements of IDEA. While IDEA explicitly requires the involvement of special education programming, implementation of Section 504 is general education responsibility (Yell 2006). Essentially, Section 504 provides *access* to an education (“to and through the schoolhouse door,” Wright and Wright 2008); however, Section 504 includes no guarantee that the individual will receive educational benefit, as specified in IDEA.

In order to determine a student’s eligibility under Section 504, schools are required to follow certain procedural safeguards related to the identification, evaluation, or educational placement of students with a disability (U.S. Department of Education, Office for Civil Rights 2010). An evaluation must occur if a parent or teacher has referred a student, if a student has a medical diagnosis, or if a student has missed an excessive number of school days due to illness. Schools must use an evaluation procedure to determine whether a student’s disability (or perceived disability) limits his or her ability to perform a major life activity, but there is no standardized protocol for how this evaluation should take place.

The FAPE provision requires that once students have been evaluated and determined to meet the criteria for Section 504, school teams must develop an individualized plan that outlines how services and accommodations will be provided. Many students who meet the criteria of Section 504 are also protected under IDEA. These students will therefore have an individualized education program (IEP) that will also constitute their written plan. If a student’s educational needs can be met with accommodations and related services that do not include specialized instruction, they do not typically qualify for special education. These students have only a Section 504 plan that reflects their needs. Finally, a number of rights and safeguards provided by IDEA are not similarly provided to individuals under Section 504, including prior written notice, rights to independent educational evaluations, and protections from permanent expulsion. Table 1

504 Plan, Table 1 Overview of major differences between Section 504 and IDEA

	Section 504	IDEA
Eligibility	Individuals must qualify under the broad definition: (1) have a physical or mental impairment that substantially limits one or more major life activities, (2) have a record of such an impairment, or (3) be regarded as having such an impairment. Need for special education is not a requirement	Students (aged 3–21) must qualify under one of the fourteen disability categories; students must demonstrate need for special education services
Major provisions	No otherwise qualified individual with disability shall solely by reason of his or her disability be: • Excluded from participation in • Denied the benefits of • Be subjected to discrimination under any program or activity receiving federal financial assistance	Procedural safeguards and the right to free appropriate public education in the least restrictive environment as defined by IDEA
Funding	No funding provided for Section 504	Both state and federal funding
Overall responsibility	Local education agency (LEA); general education	State education agency (SEA); special education

A

provides an overview of the supports and services provided under Section 504 and under IDEA.

Application in Postsecondary Education

Any postsecondary institution that receives federal funding is required to apply the regulations of Section 504 for qualifying individuals. Qualifying individuals at the postsecondary education level are those individuals with a disability who also meet the academic or technical standards that are required for admission by the institution. Individuals must also meet the participation requirements for the institution’s activity or program. FAPE does not apply to postsecondary educational settings; instead, institutions are required to provide “appropriate academic adjustments and auxiliary aids and services that are necessary to afford an individual with a disability an equal opportunity to participate in a school’s program” (US Department of Education, Office of Civil Rights 2011). The accommodations and services provided by a postsecondary institution should not alter the individual’s program in a fundamental way nor should they create an “undue burden” on the institution.

Individuals with autism who meet the requirements for Section 504 while in elementary or secondary education should recognize that they might not receive the same services or

accommodations at the postsecondary level. For example, some individuals with autism may be provided support from an educational assistant while in high school. Postsecondary institutions are not required to provide the same service because it may result in an undue financial burden to the institution (US Department of Education, Office of Civil Rights 2007). Another difference in provisions at the postsecondary level is the shift in responsibility. At the elementary and secondary school level, school districts are required to identify, evaluate, and ensure services for an individual with a disability under Section 504. At the postsecondary level, individuals must disclose their disability to the university and follow the institution’s procedures for requesting academic adjustments. Individuals with ASD must be prepared to discuss their individual needs when transitioning to the postsecondary education setting (Adreon and Durocher 2007).

Application in Employment Settings

Any employer who receives federal funding must also fulfill the mandates of Section 504 that protect qualified individuals with a disability. The disability criterion for protection under Section 504 in an employment setting is the same as in educational settings; however, the definition of “qualified” is changed. For the purposes

of employment, in order to be “qualified” an individual with a disability must be able to perform the essential function of the job with reasonable accommodation (US Department of Health and Human Services, Office of Civil Rights 2006). An employer is required to take steps to accommodate an employee’s disability unless doing so would cause an undue burden to the employer.

Workplace accommodations for individuals with disabilities are somewhat intuitive in certain situations (i.e., providing a sign language interpreter for an individual who is deaf or an access ramp for an individual with a physical disability). Workplace accommodations can sometimes be less obvious in the case of an individual with ASD but are no less important in ensuring the individual’s success in the workplace. Accommodations for individuals with autism in the workplace could include minor modifications to work materials or physical changes in the workplace that make the position more accessible. For example, an employer could make the reasonable accommodation of providing a quieter workspace that reduces distractions if such a change would be an appropriate accommodation for the individual with autism.

Future Directions

Increased Prevalence

A recent prevalence study estimated that 2–3% (1:38) of the total school-age population have an autism spectrum disorder (Kim et al. 2011). Many of these students are served in the general education setting (i.e., two-thirds of the sample in the Kim et al. study, 2011) and may not qualify for services under IDEA. This increases the likelihood that individuals with ASD will receive protections under Section 504, which has vast implications for school staff. This resurgence in 504 cases will require that school staff is adept in identifying and implementing appropriate accommodations and modifications for students with ASD – likely requiring additional staff training and expertise. In addition, an increase in litigation around 504 protections is expected as families and schools struggle to identify what accommodations

and auxiliary aids are required. For example, Section 504 does not mandate specific education programs or models nor does it require that students with ASD receive individualized instruction in specialized settings (Katsiyannis and Reid 1999). As this population ages, the demand for Section 504 protections at postsecondary settings, including universities, community colleges, and trade schools, will likely also increase. The resources required to implement these plans, both human resources and financial resources, may create new challenges for these institutions. Finally, employers will likely face similar challenges in supporting employees on the autism spectrum protected by Section 504.

Technology

The use of personal and portable technology with individuals with ASD is on the rise (e.g., iPad, iPod, personal digital assistants, communication devices) (Mechling et al. 2009). These tools are often used to support processing, communication, self-management, self-care, independent functioning, and other “major life activities” (e.g., learning and working, per Section 504). It is not clear, however, whether provisions in Section 504 provide for the procurement/use of these devices, and this ambiguity is likely to be discussed and debated in upcoming years. Though Section 504 requires that auxiliary aids such as technology are provided to individuals with specific disabilities (i.e., hearing or vision impairments) at no additional cost, there is no mention of such supports for individuals with broader developmental delays such as ASD or communication impairments as result of such delays. The fact that no funding is allocated to school districts, postsecondary institutions, or workplaces in association with Section 504 may further complicate the issue of providing technological supports for individuals with ASD.

Social Skills Instruction

Similar questions are likely to arise around the issue of social skills instruction. Because socializing and/or social functioning is described as one of the major life activities under Section 504, accommodations and modifications in this area are

recommended for individuals with ASD (Bellini et al. 2007). These may include peer-mediated strategies, direct social skills instruction, behavioral modification, self-management, and/or other evidence-based social skill strategies. Currently, however, the state of social skills instruction for individuals with ASD who do qualify under IDEA is bleak (Bellini et al.), and little is known about the status of this type of instruction for those who are protected under Section 504. It is safe to assume that services for this population would not exceed that of those who qualify under IDEA and likely also safe to assume that social skills services for the 504 protected group are close to nonexistent. As discussed above, as this population continues to increase, particularly a higher functioning group of students who may not receive services under IDEA, an increased focus on this type of instruction will fall to those implementing Section 504 plans.

7q11.23 Duplications

Stephan Sanders

Child Study Center, Yale University, New Haven, CT, USA

Synonyms

[Williams-Beuren region duplication](#)

Definition

7q11.23 duplications are copy number variations (CNVs) in which an extra copy of 1,400 kb of DNA from the long arm of chromosome 7 is present. Duplications in this region are associated with “non-syndromic” ASD (Sanders et al. 2011). The region contains 26 genes, listed below, and is flanked by two segmental duplications (stretches of near-identical DNA). These are known to increase the likelihood of a process known as non-homologous allelic recombination, which can lead to gains or losses of the chromosomal segment flanked by these repeats and account for the common breakpoints seen in the vast majority of individuals carrying duplications in this region. 7q11.23 duplications have also been seen in combination with intellectual disability, speech delay, and cardiac malformations (<http://www.omim.org/entry/609757?search=7q11.23&highlight=7q1123>).

Reciprocal deletions at 7q11.23 cause Williams-Beuren syndrome characterized by distinctive facial features, supravalvular aortic stenosis, and intellectual disability (<http://www.omim.org/entry/194050?search=7q11.23&highlight=7q1123>). Of note, these individuals also are known for highly sociable personalities. The distinctive phenotypes resulting from opposite changes in the number of copies of this region raise the intriguing possibility that the level of expression of a gene, or genes, within the 7q11.23 region plays a key role in the development and/or functioning of the social brain.

The genes in the 7q11.23 region are ABHD11, BAZ1B, BCL7B, CLDN3, CLDN4, CLIP2, DNAJC30, EIF4H, ELN, FKBP6, FZD9, GTF2I, GTF2IRD1, LAT2, LIMK1, MLXIPL,

NSUN5, RFC2, STX1A, TBL2, TRIM50, VPS37D, WBSCR22, WBSCR26, WBSCR27, and WBSCR28.

[AACAP practice parameters](#)

Definition

One of the first comprehensive guidelines to care of individuals with autism and related disorder, the Practice Parameters of the American Academy

of Child and Adolescent Psychiatry first appears in 1999 (Volkmar et al. 1999) with recommendations for ascertainment and screening, diagnosis, and clinical care. The second version (Volkmar et al. 2014) appeared 15 years later and provided updated guidance for practioners. The original version synthesized available evidence in making recommendations for care anticipating some of the findings and recommendations made by the National Research Council 2 years later (National Research Council 2001).

The initial version was intended to aide in the diagnosis and care and treatment of individuals with autism and related disorder. It provided an overview of the assessment and treatment recommendations with an emphasis on evidence-based treatment practices based on available scientific research. It also noted the need for involvement of multiple care providers with attendant issues of care coordination and so forth.

The second version was updated to reflect the considerable advances in research – particularly treatment research and practice. It focused more specifically on the strength of evidence available in support to the various recommendations in the decade and a half since the first version appeared. The second version explicitly differed in that it explicitly noted the strength of the recommendation – ranging from clinical standard (rigorous evidence), clinical guideline (strong evidence), and clinical option (some but weak or emerging evidence) and not endorsed for treatments that appeared to have no little efficacy based on available research. Explicit distinctions were made based on the strength of the evidence ranging from randomized clinical controlled trials, controlled trials with nonrandomized assignment, uncontrolled trials, and case reports. Issues like care coordination and co-morbidity were also explicitly discussed. Many of the recommendations made were also consistent with the use of the medical home model of care (Hyman and Johnson 2012).

These practice guidelines have many similarities and a few differences from other official guidelines, e.g., relative to issues of screening and early diagnosis; this guideline recommends early screen and encourages early diagnosis while others do not (see, Wilson et al. 2014; McClure 2014, for a discussion). Differences often largely

come from the standards for levels of scientific evidence explicitly adopted by the formulators.

As with all such official guides to care, recommendations should be evaluated in light of current research and practice and the circumstances of the individual case. With that, caveat attempts of this kind are most welcome as they provide clinical guidance for a range of care providers and provide basic recommendations for care.

Aarskog Syndrome

Marc B. Taub
Southern College of Optometry,
Memphis, TN, USA

Synonyms

[Aarskog-Scott syndrome](#); [Faciogenital dysplasia](#)

Definition

Aarskog syndrome was first reported in 1970 by Aarskog in a seven-patient case series. The syndrome is characterized by short stature with peculiar facies, “shawl” scrotum (the scrotal folds encircle the penis ventrally), cryptorchidism (the testis fails to descend into its normal position in the scrotum), and abnormalities of the hands and feet (Aarskog 1970). Aarskog syndrome can be inherited as an X-linked disorder caused by *FGD1* mutations (Xu et al. 2010; Volter et al. 2014) or possibly in an autosomal dominant or recessive pattern (Xu et al. 2010). Population surveys estimate that Aarskog occurs in approximately 1 per million in the general population (Gorski et al. 2000).

Intelligence ranges from normal to mild mental retardation. A normal IQ distribution has been found (Pilozi-Edwards et al. 2011). Mild learning difficulties and attention deficit hyperactivity disorder have been reported (Pilozi-Edmonds et al.). Comorbidity has been documented with autism (Schwartz et al. 2000).

Birth size is often normal. Alterations occur when individuals are 2–4 years old (Shalev et al. 2006). Until puberty, most patients are short with height at or below the third “centile.” Puberty is often delayed, but these patients do display a growth spurt in the late teens resulting in

adult height in the low-to-normal range. Final height is around the 10th “centile.” Serum growth hormone levels are reported as normal and treatment with growth hormone is ineffective. Spina bifida occulta, cervical spine abnormalities, and scoliosis have been documented (Taub and Stanton 2008).

The nose is often described as short and stubby, with a broad nasal bridge and anteversion of the nostrils. The ears are low set and protuberant. They are fleshy superiorly and referred to as “jug-handle ears.” Maxillary hypoplasia and dental malocclusion has been reported as well as a transverse crease below the lower lip (Taub and Stanton 2008). Associated ophthalmic conditions include hypertelorism, telecanthus, blepharoptosis, and antimongoloid (downward) obliquity of the palpebral fissures. Ophthalmoplegia, strabismus, hyperopic astigmatism, retinal vessel tortuosity, nystagmus, and Brown’s syndrome have also been reported.

The hands and feet are affected by this condition in several ways. The hands are often short and broad with mild syndactyly (interdigital webbing) and/or brachydactyly (shortness in comparison to the other bones and body parts). Hyperextensible joints with concomitant flexion of the distal joints (– a hallmark sign), single palmar creases, and short medially incurved fifth fingers are also found. The feet are broad and flat with metatarsus versus short, splayed bulbous toes (Taub and Stanton 2008).

Genital anomalies include a “shawl” scrotum, bilateral or unilateral cryptorchidism, and macroorchidism (abnormally large testes). Inguinal hernia (a condition in which part of the intestine bulges through a weak area in muscles in the abdomen, specifically the groin) has been found in association with the syndrome. No characteristic anomaly has been documented in females (Taub and Stanton 2008).

There are no specific therapies for Aarskog syndrome. Some features may require surgical intervention (Orrico et al. 2007).

Description

The Aberrant Behavior Checklist (ABC) is an informant rating instrument that was empirically derived by principal component analysis (Aman et al. 1985a). It contains 58 items that resolve onto five subscales. The subscales and the respective number of items are as follows: (a) Irritability (15 items), (b) Social Withdrawal (16 items), (c) Stereotypic Behavior (7 items), (d) Hyperactivity/Noncompliance (16 items), and (e) Inappropriate Speech (4 items). A total score for this instrument was not psychometrically derived and is not valid. The ABC was designed to be completed by any adult who knows the client well. This could be a parent, teacher, workshop supervisor, case worker, or informants in other roles. Depending upon reading ability, completion time varies, but most raters complete the ABC in 10–15 min the first time. Thereafter, rating times usually decline.

A revised version of the ABC was published in 2017, along with a detailed manual (Aman and Singh 2017) and freely available annotated bibliography (<https://psychmed.osu.edu/index.php/instrument-resources>). With respect to the actual content of the scale, although the wording of a handful of items was generalized (e.g., references to “the ward” and “patients” have been altered), the meaning of all items remains the same as in the original version. Subscale titles similarly underwent slight changes; “Irritability, Agitation, Crying” is now entitled *Irritability* and “Lethargy, Social Withdrawal” is now *Social Withdrawal*. Finally, substantive changes to the face sheet were undertaken in an effort to create more usable data. More general terms for school and other settings were used to facilitate comparison, as such terms are variable over time and across geographic location. Rather than querying individual diagnoses, the face sheet now requests explanations and,

where relevant, severity about various conditions that might impact behavior (e.g., sensory or physical impairments, developmental disabilities, medical diagnoses).

The remainder of the face page is unchanged from the previous version; the rater is asked to provide the client’s sex, date of birth, and the rater’s relationship to the client, and a listing of any medicines being used by the client. In the context of treatment studies, this information (other than the subject’s name and date) is often not collected.

Instructions for completing the ABC and its 58 items are found on the second page of the instrument. The period over which informants rate the client defaults to 4 weeks. However, *depending on the clinical or research needs, this period can be increased or decreased*. The instructions ask the informant to rate the client on a scale ranging from 0 (not at all a problem) to 3 (the problem is severe in degree). Further, the instructions ask raters to take relative frequency into account, such that if a given behavior occurs more than the client’s reference group (e.g., other children of the same age and sex), scores greater than or equal to 1 are warranted. The instructions also encourage informants to consider observations and reports of other responsible adults who know the client well when making their ratings. Finally, the instructions indicate that behaviors which interfere with the client’s development, functioning, and/or social relationships should be rated as a problem, even if these behaviors do not interfere with other people around the client. The 58 behavior items consume about 1½ pages of the form.

Initially, the ABC was developed primarily as a measure of treatment effects, especially as an outcome measure for pharmacological intervention. With time, the use of the ABC has expanded, and it has been employed, fairly frequently, for the following applications: (a) to examine psychometric characteristics of other instruments and/or the ABC itself, (b) to study the behavioral phenotypes of individuals with genetic and metabolic conditions, (c) to examine the effects of different environmental variables (e.g., size of housing arrangements) on behavior, (d) to characterize

the composition of subjects within studies and/or programs, (e) to assess the effects of sleep disruption on client behavior, (f) to characterize individuals with different types of psychiatric disorders, and (g) to evaluate quality of life.

There are at least 35 languages into which it has been translated, including the following: Afrikaans, Arabic, Chinese, Czech, Danish, Dutch, Filipino, Finnish, French (Belgian, Canadian, and European), German, Greek, Hebrew, Hungarian, Indonesian, Italian, Japanese, Korean, Lithuanian, Norwegian, Persian (Farsi), Polish, Portuguese, Romanian, Russian, Serbian, Slovak, Slovenian, Spanish (Colombian, Mexican, Spanish, and USA), Swedish, Thai, Turkish, Telugu (regional language of Andhra Pradesh, India), Ukrainian, Urdu, Vietnamese, and Zulu. At the time of this writing, the following language translations were revised for compatibility with the 2017 ABC revision: Afrikaans, Arabic, Canadian French, European French, Chinese (Traditional), English (USA), Filipino, Hebrew, Kannada, Korean, Norwegian, Polish, Portuguese, Russian, Spanish (Spain and USA), and Urdu.

In 2017, a single manual for the community and residential versions of the ABC replaced previous separate versions (Aman and Singh 1986, 1994). This new manual addresses an array of subjects not covered in the original manuals, including sections on giving instructions to raters, practices to avoid, and using the ABC for characterizing change at the individual and group levels. The ABC-Second Edition Community/Residential Manual (Aman and Singh 2017) gives the history of the ABC's development and elaborates upon the meanings of all 58 items. Average subscale scores and standard deviations (normative data) are provided for adults, sourced from developmental centers in the United States and New Zealand. Normative data for teacher ratings of children and adolescents in special educational classes are provided in the following formats: (a) T-scores and percentiles by sex and age, (b) T-scores with all ages and sexes combined, and (c) means and standard deviations broken out by age and sex, as well as collapsed across all ages. The group home norms are presented in

the following ways: (a) T-scores and percentiles by age (10-year groupings) and functional levels (mild, moderate, severe, and profound intellectual disability); (b) T-scores and percentiles collapsed across functional level, summarized for age alone and for sex alone; and (c) means and standard deviations broken out by combinations of functional level and age and summarized by sex alone. Normative data for parent ratings of children and adolescents with intellectual disability are provided as means and standard deviations broken out by age and sex. The manual is also a comprehensive source for information on studies of the psychometric properties of the ABC, including internal consistency, interrater reliability, test-retest reliability, criterion group validity, concurrent and discriminant validity, and correspondence of ratings with direct observation scores. We summarize some of the information contained in the manual herein. There have been about 450 scientific studies conducted with the ABC, providing a rich literature against which new work can be compared.

Historical Background

The development of the ABC grew out of a practical need for an instrument to assess treatment effects in people with DD (e.g., Singh and Aman 1981). Development of the ABC was closely modeled on the Behavior Problem Checklist of Quay and Peterson (Quay 1977) and the enormously popular Conners' Parent and Teacher Rating Scales (Conners 1969, 1970). The initial form of the ABC contained 125 items, developed after a review of residential center case records, a survey of existing instruments, and consultation with direct care staff regarding content and wording. A pilot study obtained ratings from caregivers of 418 adolescents and adults with DDs. Items endorsed for fewer than 10% of subjects were dropped, and a principal factoring method was conducted with oblique rotation, leaving 76 items. The intermediate 76-item scale was then used to rate a new group of 509 adolescents and adults.

The data from both samples were analyzed independently by a principal factoring method

followed by oblique rotation. A five-factor solution seemed most interpretable in both analyses. Items that failed to load on the same respective factors across analyses were deleted, leaving 58 items in the ultimate ABC.

Two important subsequent changes took place more or less simultaneously. First, the original ABC contained some language that was distinctly institutional in flavor (e.g., “excessively active on the ward”). This language was modified in the early 1990s (e.g., “excessively active at home, school, work, or elsewhere”) to form what was then called the ABC-community. At about the same time, investigators assessed the ABC in child samples and found that the original factor structure was maintained for children and adolescents (e.g., Marshburn and Aman 1992; Brown et al. 2002). The earlier version of the ABC was dubbed the ABC-Residential to distinguish it from the newer ABC-Community. Thus, at this stage, there were residential and community versions available, and the Community version’s structure was validated for children, adolescents, and adults.

With time, the ABC came to be used more and more in pharmacological research involving people with intellectual disability and/or autism spectrum disorders (ASDs). Other uses are described under Clinical Uses, below. Much of the published research with the ABC can be accessed through the Annotated Bibliography on the ABC (Aman 2015; available at <http://psychmed.osu.edu/resources.htm>). One important development was the adoption of the ABC’s Irritability subscale as the primary outcome measure by the Research Units on Pediatric Psychopharmacology (RUPP et al. 2002, 2005), a network of experienced psychopharmacology laboratories funded by the US National Institute of Mental Health. In two studies, the RUPP network showed that risperidone was highly effective in reducing agitated and irritable behavior for children and adolescents with autistic disorder chosen for high initial scores on the Irritability subscale. Using data from these pivotal investigations and from another clinical trial, Johnson & Johnson Pharmaceuticals obtained a clinical indication from the United

States Food and Drug Administration for the use of risperidone in children and adolescents with autism and significant agitation and irritability. At that point, it was the only medication approved by the FDA for treating patients with autism. Subsequently, Bristol-Myers Squibb Company launched two pivotal clinical trials of aripiprazole in children and adolescents with autism and agitated/irritable behavior, again with the ABC Irritability subscale as the primary outcome measure. Bristol-Myers Squibb was also able to obtain a clinical indication for its product.

These developments have made the ABC a popular choice as an outcome measure for the pharmaceutical industry when targeting behavior problems in patients with DD. However, it is important to realize that individual academic investigators were using the ABC long before it was adopted as an outcome by industry. In 2015, Bearss et al. published an experiment showing that psychosocial training, administered by parents of children with autism spectrum disorder, was highly effective in reducing disruptive behavior in the children as assessed by parent ratings on the Irritability subscale of the ABC. It seems probable that the ABC will be used widely in future to assess the impact of psychosocial treatments in children with DDs. As noted under Clinical Uses, below, the ABC has been used for approximately 450 pharmacological and non-pharmacological purposes over the last 30+ years.

Psychometric Data

There is a wealth of psychometric data on the ABC.

Construct Validity. There have been several independent factor analyses with the ABC which have supported its construct validity (a) across versions of the ABC, (b) across settings (large residential vs. small, within the community), and (c) across age groups. Most of these studies have been referenced and summarized in the *Annotated Bibliography on the ABC* (Aman 2015; freely available at <http://psychmed.osu.edu/resources.htm>), and they are summarized in Table 1.

Aberrant Behavior Checklist, Table 1 Studies of the construct validity of the ABC

Authors	Residential/ community children/adults	Number of factors	% of items on same factor (mean factor loading)	Coefficient of congruence (mdn)
Aman et al. (1987a)	Res, Adults	5 (Same)	86% (0.58)	0.88–0.96 (0.94)
Newton and Sturmey (1988)	Res, Adults	5 (Same)	78% and 81% ^a	NR
Bihm and Poindexter (1991)	Res, Adults	5 (Same)	NR	NR
Freund and Reiss (1991)	Comm, Childr	5 (Same) (parent)	91%	0.88–0.82 (0.86)
	Comm, Childr	5 (Same) (teacher)	80%	0.65–0.91 (0.81)
Rojahn and Helsel (1991)	Res, Childr	5 (Same)	NR	0.80–0.89 (0.82)
Marshburn and Aman (1992)	Comm, Childr	4 (1–4 Same)	84% (0.65)	0.87–0.96 (0.90)
Aman et al. (1995)	Comm, Adults	5 (Same)	95% (0.59)	0.84–0.97 (0.90)
Ono (1996)	Res, Childr/Adults	5 (Same)	83%	NR
Siegfrid (2000)	Comm, Adults	5 (Same)	84% (0.69)	NR
Brown et al. (2002)	Comm, Childr	4 (1–4 Same)	71% (0.51)	0.62–0.91 (0.85)
Brinkley et al. (2007)	Comm, Childr	5 (Same for low SIB subjects)	78%	NR
		4 (Subscales 2–5 same for high SIB subjects)	60%	NR
Sansone et al. (2012)	Comm, Childr/ Adults	6 (1–5 same)	76%	NR
Kaat et al. (2014)	Comm, Childr	5 (Same)	90%	NR
Wheeler et al. (2014)	Comm, Childr/ Adults	5 (Same)	97%	NR

Same, same factor composition; NR, not reported; mdn, median value

^aUsing ordinal and dichotomous coding (absent/present), respectively

As shown in Table 1, all studies of construct validity essentially verify the ABC factor structure as described in the original report (Aman et al. 1985a). Two studies failed to find the Inappropriate Speech factor in children, possibly because of a lack of participants with ASDs; it is worth noting that a very large study ($n = 1,893$) of children with ASD demonstrated excellent support for the original factor structure (Kaat et al. 2014). One study (Brinkley et al. 2007) found significant changes to the Irritability factor when subjects with high rates of self-injury (SIB) were included, but the factor structure was confirmed when these subjects were excluded.

Other Forms of Validity. The original ABC development study included several validity comparisons (Aman et al. 1985b). Concurrent validity was established through moderate correlations with existing standardized scales (e.g., the AAMD Adaptive Behavior Scale), and comparisons of criterion groups yielded predictable patterns of difference (e.g., individuals who attended formal training activities received lower subscale scores than those who did not). Further, direct observations of the individuals in their residences were well-correlated with ABC scores. Finally, compared to unmedicated individuals, those

prescribed psychotropic medications had significantly higher ABC scores on all domains except Repetitive Speech.

Subsequently, numerous studies have demonstrated the validity of the ABC, and the manual cites about 35 studies addressing validity. Examples of this include concurrent validity between the ABC and other formal instruments, including (a) the Psychopathology Instrument for Mentally Retarded Adults, (b) the Nisonger Child Behavior Rating Form, (c) Conners' Teacher Rating Scale, (d) Diagnostic Assessment for the Severely Handicapped-II, (e) Reiss Screen for Maladaptive Behavior, (f) Stereotyped Behavior Scale, (g) Teacher Report Form, and (h) The ADD-H Comprehensive Teacher's Rating Scale.

Reliability Assessments. Many researchers, especially those who conducted factor analysis with the ABC, reported alpha coefficients – a measure of internal consistency. Generally, coefficient alpha ranged from the low 0.80s to the middle 0.90s, indicating a high level of consistency.

Interrater Reliability. Many of the studies that examined cross-informant reliability are summarized in Table 2. These generally fell into the low 0.50s to high 0.60s range, which is quite adequate for both research and clinical practice. Using criteria established by Cicchetti and Sparrow (1981), these reliabilities fall into the fair to good ranges.

Test-Retest Reliability. Several studies that examined test-retest reliability are summarized in Table 3. Median reliability ranged from the mid-0.60s to highs in the 0.90s. In general, test-retest reliability was quite high, falling within ranges characterized by Cicchetti and Sparrow (1981) as good to excellent.

Clinical Uses

As noted, the ABC was developed as an outcome measure for pharmacological trials in people with developmental disabilities, and it has been used heavily for this purpose (see Annotated Bibliography, Aman 2015). However, use of the scale is not confined to research. The ABC can be used, in combination with other data-based approaches, to monitor the effects of *routine clinical care* in people with intellectual disabilities and/or ASD.

Its early use was primarily among individuals with intellectual disabilities alone, but in recent years it has been used a great deal to assess treatment outcomes in individuals with ASD. This is supported by the available data; one large study ($n = 1,893$) produced very strong evidence for the factor validity of the ABC when used in children and adolescents with ASD. However, it is worth

Aberrant Behavior Checklist, Table 2 Summary of interrater reliability studies with the ABC

Authors	Sample size	Ages of subjects	Correlation range	Median correlation
Aman et al. (1985b)	(a) 35	Adults	0.54–0.67	0.59
	(b) 40	Adults	0.51–0.88	0.71
Aman et al. (1987b)	(a) 28	Adults	0.52–0.74	0.60

noting that although several subscales assess features of ASDs (e.g., Social Withdrawal, Stereotypic Behavior, Inappropriate Speech), the ABC was not intended to be a measure of overall autism severity.

As research on specific genetic conditions becomes more common, investigators have attempted to identify syndrome-specific factor structures rather than employing the validated existing structure. This practice is likely to yield unstable results, and researchers are cautioned against this practice (Aman and Singh 2017). Recently, Aman et al. (2020) analyzed extensive data from participants with fragile X syndrome and concluded that the classical scoring algorithm, as presented in the *ABC Manual*, is the optimal way of presenting ABC results.

Periodically, the ABC had been used to assess the effects of behavior intervention, both in formal research (Aman et al. 2009; Bearss et al. 2015) and in everyday care. Obviously, it is important to document the efficacy of such treatment. The ABC has been used to select participants for various forms of research intervention, especially pharmacological investigations. It may serve a similar role in routine clinical care to identify individuals who warrant preventive care and/or

active intervention. As noted earlier, the ABC has been used to monitor behavior in those experiencing transition, such as moving from one living environment to another. It has also been used to assess co-occurring behavioral issues in people with genetic or metabolic syndromes, and this is another likely area of clinical application.

The ABC has primarily been used to assess school-aged children, adolescents, and adults through late middle age. The largest psychometric study of the ABC in preschoolers (*n* = 556, Kaat et al. 2014) produced convincing evidence that it is valid for use in this age group, at least for those with ASD. Although there have been a few studies among elderly people, its utility here has yet to be properly and thoroughly established.

To conclude, the ABC is used to measure and document changes in behavior. These can be changes associated with pharmacological or behavioral intervention or those instigated by environmental alterations. The ABC appears well-suited to assessing a range of ages extending from school-age through late middle age. It has been useful for characterizing the behavior of people with ASD, ID, and a multitude of developmental disability-specific syndromes.

Definition

A scale used by physicians for evaluating and monitoring abnormal movements such as those associated with tardive dyskinesia which rates the severity of abnormal movements from 0 to 4. The scale is used every 3–6 months to monitor patients taking antipsychotic medications for the development of movement-related side effects. The scale was developed by the Psychopharmacology Research Branch in 1975 and is currently in the public domain.

Abolishing Operations

Amanda P. Laprime

The Center for Children with Special Needs,
Glastonbury, CT, USA

University of Rochester Medical Center,
Rochester, NY, USA

Definition

Abolishing operations (AO): a general term to describe antecedent events which momentarily decrease the reinforcing or punishing effectiveness of a consequence and therefore alter the future frequency of behavior related to that consequence. AOs, in conjunction with establishing operations (EO; see establishing operation), fall under the greater omnibus term, motivating operation (MO; see motivating operations). AOs involve events which result in a decrease in the effectiveness of a reinforcer or punisher when delivered contingent on a behavior. There are many unconditioned abolishing operations identified in humans. Satiation of food, water, sleep, activity, oxygen, and warmth or cold all function

as abolishing operations for related behavior and reinforcement (Cooper et al. 2007). For example, having just eaten lunch functions as an AO for food as a reinforcer which momentarily decreases any behavior reinforced by food.

Historical Background

Skinner (1938) discussed abolishing operations under the framework of “Drive” and “Drive Conditions,” noting that satiation has an abative effect on behavior. Original work around motivation combined EOs and AOs into one general category. More recently, the AO has been defined and studied as a motivative variable in its own right (Laraway et al. 2003; see motivating operations for a further discussion of the evolution of motivating operations).

Current Knowledge

The concept of the AO has been influential to behavior interventions for individuals with autism spectrum disorders (ASD). The functional assessment of behavior has clearly demonstrated the significance of reinforcement for challenging behavior. Many research studies have focused on reducing challenging behavior by teaching new behaviors which can result in the same reinforcer. Interventions that rely on an AO analysis differ from consequence-based interventions in that they involve the antecedent. Specifically, interventions involving the AO are referred to as antecedent interventions. Antecedent interventions modify or remove the environmental events which precede behavior, to decrease or remove the likelihood of the behavior occurring in the future (Kern and Clemens 2007). An intervention which relies on an AO would seek to abolish or reduce the value of a reinforcer. This reinforcer value-altering effect (Laraway et al. 2003) would subsequently result in a decrease of the target behavior.

For the remainder of this entry, interventions relying on the AO for their effect will be referred to as *AO-based interventions*. For example, an individual with a history of overeating at parties

may instead eat prior to attending a party. This intervention (i.e., satiation of food) would create an AO for food as a reinforcer, thereby decreasing the probability of overeating at the party as previously compared to when an EO for food was in place. The analysis of AOs has successfully contributed to the area of behavior assessment, interventions to reduce behaviors maintained by automatic reinforcement, and interventions to reduce behaviors maintained by social (i.e., positive or negative) reinforcement. These are discussed in detail below.

The Role of AOs in Behavior Assessment

Functional behavior assessment (FBA) and functional analyses (FA) help clinicians to understand how a behavior looks and functions in the environment. These assessments set the foundation for individualized interventions in clinical settings. Furthermore, they have become a “best-practice” component of any program which involves behavior intervention for individuals with ASD. Iwata et al. (1994) established functional analysis (FA) technology to better understand the unique environmental variables that evoke and maintain behaviors of interest. An FA rotates across a variety of conditions which involve an EO for challenging behavior (i.e., demand, alone, denied access, attention). One important component of all functional analyses is a “control” condition (i.e., play condition). In a control condition, there are preferred items (i.e., toys) available, no demands, and social interaction delivered on a time-based schedule. The control condition is specifically set up to function as an AO for challenging behavior. Behavior should not be evoked in this condition unless other reinforcers or processes maintain behavior. Recent research has conceptualized that turning behavior “off” in the control condition (by identifying the relevant AO variables) is just as important as turning it on across other conditions (by identifying relevant EO variables, Hanley et al. 2014). Information about the environmental events acting as an AO for challenging behavior has guided the development of interventions to reduce challenging behavior in individuals with ASD.

Reducing Challenging Behavior with AO-Based Interventions

In addition to contributing to behavior assessment, AOs have been instrumental in developing effective treatment plans. AO-based interventions have demonstrated efficacy with challenging behaviors maintained by automatic reinforcement, as well as those maintained by social reinforcement.

Automatic reinforcement is defined as that which is not mediated by another person. For example, when you feel an itch, scratch it, and it goes away, the reinforcer (i.e., removal of the itch) does not rely on another person. Therefore, the behavior is automatically reinforced. Meaning, in the future, when you feel an itch, you will continue to scratch, because discomfort is removed. This differs from a situation in which you feel an itch, ask someone to scratch the spot, and they scratch it. In the latter scenario, reinforcement is delivered via an individual and is therefore social mediated. Stereotypic behavior, which involves repeated, restricted, and repetitive responses, is frequently maintained by automatic reinforcement. In this case, the behavior may be reinforced by the feeling, sound, or some other quality it itself produces. Automatically maintained challenging behavior can interfere with prosocial repertoires for individuals with ASD and is often difficult to decrease. Historically, interventions targeting behaviors maintained by automatic reinforcement have had limited impact or have necessitated aversive consequences for their effect. When effective, interventions for these types of behaviors often require intensive adult support, which does not lead to maintenance and generalization of suppressed responses (Laprine and Dittrich 2014). AO-based interventions have provided an alternative way to reduce automatically maintained challenging behavior. Examples of these interventions include noncontingent reinforcement (NCR) and pre-session access to reinforcers. The commonality across these interventions is that a known reinforcer is delivered proactively. This differs from procedures which contingently omit reinforcement (i.e., extinction) or deliver an alternate reinforcer (i.e., differential

reinforcement). By satiating an individual on a reinforcer prior to it occurring, an AO may be established which decreases the frequency of the behavior. For example, if a child has previously engaged in repeated scripting of their favorite television show (challenging behavior) because of the preferred sound it creates (reinforcer), delivering access to those sounds proactively may reduce echolalia for a duration of time following the reinforcer delivery. This would be an example of pre-session access to a reinforcer. NCR procedures involve delivering a known reinforcer on a time-based schedule, unrelated to the occurrence or nonoccurrence of a behavior (Cooper et al. 2007). For instance, if a child throws an object (challenging behavior) because of the sound it creates (reinforcer), an AO may be established by proactively providing set times in which designated objects can be thrown to create the same sound. This intervention would create an AO for the sounds as a reinforcer and subsequently reduce throwing behavior for a period of time following intervention. NCR has successfully reduced a variety of topographies of behavior maintained by automatic reinforcement. These include but are not limited to rumination (Carroll et al. 2011), vocal stereotypy (Lang et al. 2009), self-injury (Horner et al. 1991), mouthing (Simmons et al. 2003), as well as behaviors maintained by social reinforcers (discussed in more detail below). Pre-session access to reinforcers has been demonstrated to reduce echolalia (Laprine and Dittrich 2014), vocal stereotypy (Berg et al. 2000; Rispoli et al. 2013), property destruction (O'Reilly et al. 2009), and more general challenging behavior such as aggression or tantrums (Chung and Cannella-Malone 2010; Lang et al. 2010).

AO-based interventions have also been prominently featured in the literature on challenging behaviors maintained by social reinforcement. Social positive reinforcement involves the addition of a preferred stimulus following a behavior (such as attention or a tangible item), while social negative reinforcement involves the removal of something aversive following a behavior (such as a difficult academic assignment). Both positive and negative reinforcement involve reinforcement

that is mediated by someone else. For instance, if a child is presented with academic work, rips it up, and someone takes away the academic demand, the escape (negative reinforcement) is mediated by another person. Several of the same AO-based interventions previously discussed (i.e., NCR and pre-session access to reinforcers) have been used with behaviors maintained by social reinforcement. Vollmer et al. (1995) demonstrated that noncontingent access to escape reduced self-injurious behavior maintained by escape from demands for two young men with developmental disabilities. The researchers provided escape from instruction on a time-based schedule (i.e., every 2 min). The intervention reliably reduced self-injurious behavior across both participating, and over time, the researchers increased the schedule of escape to one that was more naturalistic (i.e., every 10 min), without the reoccurrence of self-injury. Many studies have demonstrated the efficacy of NCR to create AOs for challenging behavior maintained by social negative (Butler and Luiselli 2007) and social positive (Derby et al. 1996; McComas et al. 2003) reinforcement. Along this line of research, several studies have focused on creating an AO for escape-maintained behavior during academic instruction with children with ASD. All interventions involve pairing an environment or environmental situation with high levels of reinforcement. These AO-based interventions have included errorless instruction (Ebanks and Fisher 2003), rate of instruction (Roxburgh and Carbone 2012), stimulus demand fading (Pace et al. 1993), and the high-p request sequence (Mace et al. 1988). One example of an AO-based intervention to decrease escape-maintained problem behavior during academic work involved the technology of pre-session pairing (Kelly et al. 2015). While pre-session pairing is often described a best-practice approach for working with children with ASD, Kelly and colleagues were the first to systematically evaluate the degree to which the intervention created an AO for escape from demands as a reinforcer. In this study the authors provided access to highly preferred reinforcers, in the presence of an instructor, for a set amount of time prior to academic instruction. They found that the intervention

created an AO for escape and attention maintained challenging behavior during academic instruction for three children with ASD who engaged in a variety of challenging behavior (i.e., self-injury, refusal, aggression, and elopement). All participants had decreased levels of challenging behavior and increased responding to instruction following pre-session pairing sessions. Across all studies referenced here, AO-based interventions not only reduced target behaviors but resulted in increased participation with instruction for participants.

A series of studies have also employed the AO to reduce challenging behaviors maintained by social positive reinforcement (Edrisinha et al. 2011; Derby et al. 1996; McComas et al. 2003; McGinnis et al. 2010). McGinnis and colleagues (2010) found that providing pre-session attention to three children with ASD and other developmental disabilities reduced their challenging behavior (self-injury, aggression, property destruction, and tantrums), for up to 15 min in subsequent test sessions. The authors compared a low-AO pre-session condition (with less pre-session exposure to attention) to a high-AO pre-session condition (with more pre-session exposure to attention). The results of the study demonstrated that while both AO conditions resulted in lower levels of problem behavior following exposure, the high-AO sessions resulted in the lowest levels. Marcus and Vollmer (1996) found that noncontingent access to tangible items effectively reduced aggressive and self-injurious behavior in three young children with ASD (two of the participants) and down syndrome (one participant). These studies are example of those which have contributed to the research on AO-based interventions to decrease potentially dangerous and intense challenging behaviors. Importantly, behavior reductions were achieved in many of these studies without the need for punishment or extinction-based interventions.

AO-based interventions have become a popular choice for reducing challenging behaviors for children with ASD. As previously stated, AO-based interventions fall under the umbrella of antecedent interventions. AO-based interventions provide an alternative to interventions that

require intensive schedules of reinforcement, punishment, or extinction (Smith and Iwata 1997). Importantly, these interventions do not rely on another person to respond to each instance of behavior. For this reason, AO-based interventions may require less resources than other interventions such as differential reinforcement. Furthermore, they reduce the probability of a behavior occurring at all, which is important for potentially dangerous behavior (such as self-injury or rumination). Lastly, AO-based interventions may be easier for individuals to implement and reduce the need for hands-on, intensive intervention (Vollmer et al. 1995). One limitation to AO-based interventions is that their impact is relatively short-lived. The reason for this is that MOs function along a continuum. Immediately following the delivery of a reinforcer, an individual is satiated (AO) on that reinforcer. The AO (i.e., satiation) reduces the probability of the behavior related to the reinforcer occurring. As time increases from the delivery of the reinforcer, the satiation will wane and the individual will enter a state of deprivation. This change in states of motivation will create an establishing operation (EO). The EO, by nature of its effect, will increase the probability of the behavior reoccurring. This analysis is important in understanding the long-term effects of AO-based interventions (Michael 2000). Another limitation to these interventions is that they do not change the contingencies which maintain challenging behavior. Therefore, the effect of an AO-based intervention is limited unless the AO remains in place (Iwata et al. 1993).

Future Directions

An understanding of AOs has been demonstrated to be an effective component of interventions to reduce challenging behavior for individuals with ASD. Continued research and application of interventions based in the conceptualization of AOs are necessary to expand the analysis of behavior as it relates to these areas. It is important that the longevity and generality of these interventions continue to be assessed in the literature and in practice with individuals with ASD.

Absence Seizures, Second Edition

Jennifer M. Kwon¹ and Ria Pal²

¹Department of Neurology and Pediatrics (SMD), University of Rochester, School of Medicine and Dentistry, Rochester, NY, USA

²University of Rochester School of Medicine and Dentistry, Rochester, NY, USA

Note: In 2017, the International League Against Epilepsy (ILAE) revised the naming of seizures to make them more understandable. Terms like “petit mal” and “pyknolepsy” be avoided

Short Description or Definition

An absence seizure consists of staring as the behavioral change which accompanies abnormal generalized electrical activity in the brain. The

electrical brain activity seen in “typical” absence seizures is generalized 3-Hz spike and wave discharges. Absence seizures are brief (usually less than 15 s) and do not usually result in falling, loss of muscle tone, or jerking of the arms and legs.

Categorization

Absence seizures are categorized as primarily generalized seizures. Childhood absence epilepsy has an onset between 3 and 8 years of age, and juvenile absence epilepsy has onset after 10 years.

Epidemiology

Childhood absence epilepsy (CAE) has an incidence of 6.3–8/100,000 in children less than 15 years of age, and the majority are girls.

CAE represents about 10% of all epilepsies and as such is among the most frequent types of epilepsy. Other seizure types may also occur in children with CAE. It is more common to have other seizure types with juvenile absence epilepsy (JAE).

Absence epilepsy is not reported to occur with greater frequency among children and youth with autism spectrum disorders. It has been associated with specific genes related to GABA function and calcium channel function.

Natural History, Prognostic Factors, and Outcomes

Absence seizures occur most commonly in people under age 20, usually in children ages 6–12. Children who develop typical childhood absence epilepsy (CAE) are usually normal in their development. The seizures are brief, lasting just seconds, but can occur many times a day. They can typically be triggered by hyperventilation. Many children can become seizure-free but the percentage varies. It has been reported that up to 90% of affected children will be seizure-free by adolescence. There may be school and learning difficulties, particularly with verbal memory, seen in patients with CAE. Inattention is reported.

When absence seizures have atypical features, such as EEG findings that are not simply 3-Hz spike and wave, or when the seizures can also be associated with convulsions or myoclonic jerks, it may be harder to become truly seizure-free.

Clinical Expression and Pathophysiology

Absence seizures are related to GABA and voltage-dependent calcium channel functions. Thalamocortical tracts are implicated. Most absence seizures are considered idiopathic or of unknown etiology.

While a genetic association has been identified for a small number of patients, absence epilepsy is idiopathic at this time. It has been reported in children with Angelman syndrome but has not been specifically associated with autism. It may be difficult to clinically differentiate staring episodes from behaviors that occur for other reasons in individuals who are inattentive, who stare, and who might have motor mannerisms on the basis of autism. Absence seizures may be accompanied by a glassy expression (look absent), and affected children may drop things. They may have brief eyelid fluttering or other automatic, subtle movements.

Evaluation and Differential Diagnosis

Evaluation is indicated if staring episodes lasting 5–30 s are observed in children or youth. They may or may not have repetitive motor movements. They will not turn to their name or alert when touched. People do not recall absence seizures.

EEG is the diagnostic study of choice. Characteristic general synchronous, bilateral 2.5–4-Hz spike and slow-wave discharges are seen. Generalized activity on an EEG means that abnormal and synchronized epileptic activity is detected by all EEG electrodes (or most of the cortical surface). If they are frequent enough, a conventional EEG will capture an episode. If less frequent, prolonged monitoring with video may be necessary to identify if a staring episode is a seizure.

As noted, it may be difficult to clinically distinguish absence seizures from inattention,

overfocus, and staring in patients with ASD who might also have stereotyped movements. They are sometimes difficult to distinguish from atypical absence epilepsy and may occur with other seizure types as well. Absence seizures very rarely explain inattention in patients with ADHD.

Since absence epilepsy may result in inattention, there may be a negative effect on school work and social interaction. This may also result in psychosocial stress. The medications used to treat the seizures may further impact attention and learning. Decision on what medication to use must balance all of these factors.

Treatment

The medications used to treat petit mal or absence seizures include ethosuximide, valproic acid, and lamotrigine. The first two have equivalent efficacy but ethosuximide is the initial monotherapy of choice due to fewer cognitive side effects. Forty to seventy percent of children are seizure-free within 4–5 months of therapy. In small studies, topiramate monotherapy has been ineffective for absence seizures. The utility of other anticonvulsants, such as levetiracetam and zonisamide, are under study. Some children with absence seizures that cannot be controlled by any combination of medicines may benefit from a ketogenic diet.

Academic Skills

Rita Jordan

School of Education, University of Birmingham, Edgbaston, Birmingham, UK

Definition

Academic skills have the same meaning within the field of autism as without; they refer to skills in subject areas that form the academic curriculum, available to all children in that country. Increasingly, children and young people within the autism spectrum are entitled to the skills, knowledge, and understanding available to others as a matter of human rights, although there may be problems in exercising these rights where there are additional inherent problems (such as language or intellectual difficulties) or behavioral difficulties. There are also common comorbid conditions that may occur with autism (such as specific learning difficulties: dyslexia, dyspraxia) that may cause particular academic difficulties. However, there are no reasons why individuals with autism should be excluded from any academic area as a result of their autism alone. There may be difficulties in accessing certain

subjects because of the way they are taught or the physical or social context in which they are taught. As with others, success in acquiring academic skills in autism depends on intellectual level, particular talents, and interests, as well as an autism-friendly teaching approach.

Historical Background

Although Kanner (1943) had recognized the biological base of autism, he was later influenced by current psychological theories, which saw autism as a form of childhood schizophrenia with treatment confined to therapy for the child, or the family, depending on the theory of causation adopted. Thus, for two decades following the identification of autism, most children with autism were excluded from academic education of any kind. If there was treatment, it was of a clinical and/or therapeutic kind. It was left to a few pioneering schools (in the UK and Denmark) to demonstrate that these children were able to learn and benefit from education, although even then, the specialist curricula of such schools were largely concerned with teaching adaptive behaviors and practical occupation skills; academic skills were still regarded as largely inappropriate.

Two things changed this picture. Wing (1988) introduced the notion of an autism spectrum that included children and young people with average or above average intellectual ability and good structural language skills (introducing the term “Asperger’s syndrome” to describe such children). It became clear that many of these children (albeit often undiagnosed or misdiagnosed) were already in mainstream schools. Secondly, there grew a worldwide movement for the social inclusion of all children in education with the same entitlement to the culturally valued skills, knowledge, and understanding available to other children and young people in that culture. Inclusion is not about integration alone, where a child may be “allowed” access, but about the designing of curricula and educational systems that take account of all children, in all their diversity and needs, from design to implementation. This is an ideal that is still a “work in progress” in most countries,

but it did open the door to the realization that many children on the autism spectrum could and should benefit from access to the full academic curriculum. The goal was to identify barriers to this process and to seek ways of overcoming them.

The effects of these developments were that children with autism in many countries began to be included in special needs legislation that recognized their entitlement to a broad and relevant curriculum, including academic skills. This did not always mean mainstream education since many children had learning and behavioral difficulties that made full integration problematic, and staffs in mainstream schools were then largely unaware of the special needs of those with autism, and lacked strategies to meet those needs or help the pupils overcome their many barriers to learning. However, special schools often (although not universally) adapted their curricula to include access to academic skills that enabled all their pupils to participate in the national curriculum of their country, albeit often adapted to individual needs. At the same time, as more children with autism were learning to be included in the general educational system available to others, a contrary movement developed from a clinical perspective, which claimed that education for those with autism should first focus on the remedial aspects, training the child in basic adaptive functioning as a precursor to any other form of learning. This was introduced with preschool children and made the claim that such programs would be so successful in remediating core difficulties that no special measures to access the academic curriculum would be needed. Some children appear to have benefited significantly from such intensive behavioral intervention at an early age, although there is no follow-up showing the later effects on learning academic skills (except of the most basic skills of reading and writing). However, research shows that not all children benefit equally (Parsons et al. 2011) and that for some children (especially those of higher ability) it is not relevant to their academic learning. The emphasis on developmental, as opposed to academic, skills, however, has influenced some educational practice, especially in special schools.

The growth of autobiographies of those with autism has also had a profound effect on the understanding of what might be appropriate curricular content for those with autism. Many “successful” individuals with autism demonstrate that success (especially in terms of vocational success and being able to achieve financial independence) depends on building skills and expertise in particular academic subjects at least as much as overcoming supposed “deficits” in functioning. The influence of special interests in guiding and developing academic skills has been shown to be even more important in autism than with other learners and “interest-led” curricula are being developed. Information technology (IT) is not a universal interest of those with autism, but it has been shown to be a valuable medium for learning for many (Murray and Aspinall 2006) and its increasing role in the academic curriculum of many schools has aided participation by those with autism.

The end result has been that many more students with autism are succeeding academically, gaining qualifications at school, and entering further and higher education. Although most people with autism will continue to need understanding and some support even in universities, greater numbers are able to qualify. Sadly, social difficulties and levels of anxiety remain high and may interfere with future job prospects and quality of life (Gelbar et al. 2014). Yet the chance to pursue areas of interest through academic study does of itself improve life for those with autism. Some do attempt to stay within academia, gaining more and more qualifications. Sometimes this is a positive outcome, but for some, it reflects fear and anxiety about moving on from university to the wider world. Those who do succeed provide role models for younger students but also help reinforce the value of academic skills to people with autism. For those with additional learning difficulties, high academic achievement may be out of reach, but academic skills still have relevance in their education. Daily living skills may have a higher priority, but interest and development are fostered by participation in academic tasks and basic academic skills are needed to live a life of dignity and some independence.

Current Knowledge

A study by the Council of Europe a few years ago (Jordan 2009) showed that almost all countries across Europe “included” children and young people with autism within their education systems, although the definition of “education” was varied. For some countries, especially where children with autism had additional learning difficulties, “education” was very like what other countries might describe as “clinical” practice. This was true of some countries that had developed treatment services for people with autism for many decades and where standards of individualized treatment were very high. It is almost as if successful “treatment” is seen as an alternative to inclusive education for some of these children. Even in countries where official policy is for full inclusion for all children with autism (including those with additional difficulties), there remain considerable barriers to its full and successful implementation (Jordan 2008), mostly related to insufficient understanding of autism in mainstream schools. Many developed countries have made significant efforts to increase understanding of autism across the education service with online in-service training of staff and the growth of accredited programs in autism studies.

Even where inclusive practice is well developed, there are usually ways of excluding some children from some aspects of the academic curriculum, where these are not considered relevant to the individual pupil. There will always be some children and young people for whom it is more advantageous to concentrate on a narrower band of academic subjects than is generally taught as part of the national curriculum. This might be because of specific difficulties with subjects that are not considered vital for that individual’s development and future quality of life or it may be because dropping some subjects will allow concentration on other subjects that are more interesting and/or relevant to the individual. The problem is that not all such decisions are evidence based. Ultimately, each decision should be an individual one and there is no good scientific research that can decide which academic subjects will be of benefit to those with autism and which will not.

In fact, it is unlikely that such generalized statements will apply across such a heterogeneous population. Too often, such decisions are made based on assumptions that have not been tested.

Academic Subjects in Relation to Autism

Mathematics: It is often assumed that mathematics will be a strength in autism but this is too broad an assumption. The early stages of mathematics (computation and rule-governed stages) are often areas of strength in autism. However, later stages may produce problems and the aspects that cause problems will vary according to learning style. For visual learners, geometry and graphical work may be strengths but for those who are not visual thinkers (and visual thinking is not universal across the spectrum) this may be a particular difficulty rather than a strength. For the larger group of visual thinkers, algebra rather than geometry may be a problem. Algebra represents a problem because to understand algebra, one has to understand reversibility of operations, which, in turn, requires explicit working memory ability – often a problem in autism. A recent development is software (GRID algebra: Hewett 2016) that makes these internal operations visible (the child can see what operation has been performed and so needs to be reversed), but this awaits evaluation with children with autism.

Even computation skills may be compromised by context and time constraints. When a numeracy program was introduced as a core part of the National Curriculum in the UK, it was expected that this would pose no particular problems for those with autism. But this program emphasized mental arithmetic, conducted at speed in a class context. This proved disastrous for many with autism who could neither concentrate fully in such a group context nor access their answers at speed. It became clear that implicit knowledge of the answer might be there (and could be accessed given time) but there were problems in making the answer explicit and only responding when directed to (inhibiting responses if the teacher did not direct the question specifically at them). As a result many children with autism began to fail at a subject they had previously felt confident in, with disastrous effects on their morale and general learning ability.

One aspect of mathematics, however, has largely unrealized potential in autism: statistics. It is well established that people with autism struggle with uncertainty and that many behavioral issues arise when expected circumstances change or when people find it hard to give definite answers and keep to them. Being told that something “may” happen or that we “will see” if an event unfolds will generally result in much distress in individuals with autism and even challenging behavior. Yet clearly not all of life’s events can be predicted with certainty and people with autism need to be prepared for situations that change. As long as the individual is intellectually able enough to understand, this can be solved by introducing the notion of probability and statistics. In reality, saying that an event has a 90% chance of occurring tomorrow and a 10% chance of not occurring may have little basis in fact, but the numbers seem to make it more acceptable to the person with autism than if one just said it might or might not happen. Degrees of certainty can be refined as the child is taught the variables on which the occurrence depends and the degrees of confidence in that statement. Using such numbers to replace indecisive language not only helps reduce distress and consequent challenging behavior but also gives an acceptable language of numbers for describing and predicting the world. In some cases it can lead to a lifelong interest in statistics and even an occupation using statistics.

On a less positive note, a special ability to calculate at speed may seem like an expression of a high level of mathematical ability that could be utilized in a work situation or be useful for increasing academic ability. But high-speed calculators may have no insight into how answers are reached, that is, no ability to reflect or monitor their own learning. This can be a great drawback when it comes to examinations, where it is important to show working to demonstrate understanding: the actual correct answer carrying less weight than this working out. It can also prevent effective vocational uses of this computational ability. People with autism can sometimes have the capacity to add up a shopping list mentally, for example, but cannot follow the sequential process of recording each item on a cash register. The sad

fact is that no shopper will trust the mental calculations of someone who does not record them on a cash register so an apparent strength ends up having little value.

Literature: Just as mathematics may be assumed to be universally strong in autism, so literature may be seen as a universal problem, but that is equally untrue. Written language is often easier than speech for people with autism, because it does not vary so much between people and situations. Some children with autism come to develop speech through written language for this reason, reversing the typical progression of being able to tell a story by arranging pictures in sequence before learning to read. It is not the sequencing that is a difficulty but the “making sense” of the underlying narrative. It has been suggested, with some research support (Bruner and Feldman 1993; Losh and Capps 2003), that people with autism struggle with many aspects of narrative: understanding the basic narrative structure of events (steady state, event, restoration of the state marked by a coda); telling the gist of an event rather than verbatim details; understanding different roles within an event; keeping track of protagonists within a story by appropriate pronoun use; understanding emotional responses of protagonists; understanding agents and intentional acts. Reading in autism often emerges through reading instructions in computer games or on videos. However, this ability to read short phrases or to memorize large chunks of text is very different from the ability to make sense of longer connected texts such as fictional stories or novels. This is especially true if, as is often the case, there is associated dyslexia in autism. It is paradoxical that individuals with autism may also be hyperlexic, in that they can “read” large chunks of text but in a rote manner, without being able to perceive meaning in the text.

Less commonly, some people with autism are verbal thinkers and have good verbal ability. For these individuals their verbal ability may help with their understanding of the world. For example, linguistic structure can help distinguish actual from reported, or imagined, events and this has been shown to be a factor in some able people with autism learning to develop an understanding of mental states (Theory of Mind). Inasmuch as

literature does involve some of the key difficulties in autism, teaching literature can also be seen as an opportunity to address some of these difficulties: understanding motivations, intentional actions, and their consequences. In written form, these ideas can be addressed at the child’s own pace, rather than trying to be grasped in real-life situations which may pass too quickly and which may be harder to interpret in terms of key events and characters. Literature can provide a structure with which to interpret events and some approaches use written scripts to help the person with autism understand, prepare for, and carry out social actions.

When it comes to writing, there may be dyspraxic or other motor or sensory problems that hinder the development of handwriting skills. It is useful to learn some basic handwriting skills, where possible, and teachers need to take advice from occupational therapists to look at supports (e.g., in posture, in pencil grips) to make this happen. Since typing or touch screen technology means that “writing” (or at least communicating in a visual form) is more accessible to children even with the most severe motor problems, difficulties in handwriting should not be allowed to hinder the expression of ideas. Such technological solutions have enabled some people with autism to demonstrate their ability to think and to express themselves, when it would otherwise have been assumed they were incapable of doing so. Using writing (or an equivalent form), children can also be taught skills such as making a précis of a text, which helps them understand how to extract meaning from a text in a very tangible way.

History: Whether or not history presents a problem for people with autism depends on the nature of the curriculum and how it is taught. If it is presented as a list of facts that can be memorized, then most people with autism (unless they have severe learning difficulties) will manage this without difficulty. However, unless there are clear rules, it can be more difficult to try to assess possible causes for certain events or, even more problematically, try to imagine alternative outcomes. The most difficulties for those with autism, however, are caused by history teaching that requires the pupils to imagine, for example, what it might feel like to have been a Roman

soldier on Hadrian's Wall, or a pilgrim arriving in North America. As with literature, the very fact that history may present some difficulties for pupils with autism can also be seen as an opportunity for teaching. It can be a chance to make explicit some of the things that might affect how someone might feel. This allows pupils with autism to learn more about emotions and to develop a cognitive frame for developing empathy (or at least, sympathy). This does not lead to typical intuitive empathetic understanding, but research shows that a cognitive approach supported with many examples in practice can provide the best approach for people with autism to develop some understanding of others (Mesibov 1986; Ozonoff and Miller 1995); the explicit discussion of motivation and the effects of actions in history may provide this.

Geography: Many individuals with autism prefer to be outdoors rather than confined in buildings (Evans 2015), so they appreciate opportunities to explore their natural environment. For some, this will extend to interest in the geographical features of the outdoors environment and particularly aspects of physical geography. Geographical features of the environment can be explored and explained through laws governing forces of climate, water, volcanoes, particular rock structures, and so on. All of this can provide a logical way of understanding the physical aspects of the environment, without the need for social understanding. On the other hand, the study of populations in social geography can enable some understanding of groups of people, if not of individuals.

Science: Science (and engineering) is usually considered to be one of the most accessible academic subjects for individuals with autism. People with autism are often, mistakenly, thought to have problems with abstract concepts, which would make the abstract concepts of science difficult to master. However, it is not "abstraction" as an explicit description of a concept that causes problems in autism; rather it is the implicit process of abstraction through which everyday "fuzzy" concepts are normally acquired from experience that causes the problems. People with autism therefore have problems with everyday concepts, but

scientific concepts do not rely on this process of abstraction; they are defined explicitly by criterial features and so fit the learning style of those with autism. It is the specificity and explicitness of science that makes it an attractive choice for those with autism. However, there can be some difficulties with the scientific process. People with autism find it difficult to tolerate uncertainty so the scientific method of hypothesis testing can be a problem for them. Once again, however, the process of scientific enquiry can help by specifying the conditions under which facts are established and by being rule governed. Statistics can also help with this understanding and the acceptance of uncertainty.

Foreign Languages: There is a common view in education that, if there is pressure on the curriculum for those with autism because of the need to provide education in social and life skills, then learning a foreign language can be dropped to provide that curricular space. The argument is often made that the person with autism has struggled to master his/her first language so it would be a waste of time to attempt to teach them a second language. There may well be individual cases where this is the correct decision, and certainly curriculum subjects need to be prioritized. But such decisions should always be on an individual basis – not on an assumption that all pupils with autism will struggle with a foreign language. Some may indeed have struggled to acquire their first language and may still have problems with receptive language and with the pragmatic uses of language. A foreign language, however, is not generally taught in the way that a first language is acquired. Everything is made more explicit, so that the processes and structures of the language are much more apparent to the pupils with autism than the implicit understandings that characterize first language acquisition. It may be the first time that students with autism have understood these aspects of language and not only will this make the foreign language easier to acquire but may also help with the understanding of their first language.

In addition, learning a foreign language in a mainstream school is often the only opportunity given to the pupil to be taught everyday social

skills such as greetings, social rules and different language styles, adjusting language to context and useful skills like waiting in restaurants, gaining attention, expressing regret, asking directions, and so on. The fact that these vital social skills are being taught in a foreign language is a minor problem compared with the general failure in mainstream schools to address these important areas of learning at all. Once again, many individuals with autism become very interested in, and skilled at, foreign languages and some are able to obtain employment through acquiring this academic skill.

Few schools remain that teach classical subjects such as Ancient Latin and Greek, but such “dead” languages are also often highly appealing to people with autism. These dead languages do not have the pragmatic learning opportunities of modern foreign languages, but they do offer “pure” academic skills. Because these languages are no longer live, they do not vary according to deictic factors like time, place, and person. Thus, they can be learnt as a system, almost divorced from social meaning, and one that remains unaltered over time.

Information Technology: This relatively new academic subject is not universally attractive or accessible to all individuals with autism, but it has made academic study accessible to many people with autism as well as being a useful tool for accessing other parts of the academic curriculum. Computers can provide a patient, controllable, self-paced, and, above all, nonsocial environment for learning and thus provide access to a large part of the academic curriculum. Information technology can be a rigorous academic subject in its own right also and offer a potential vocational opportunity for many individuals with autism.

Psychology: A minority of schools offer psychology as an academic subject. Although few people with autism will be suited to a career in psychology (in spite of the fact that some have done so), it can be a valuable subject to study as an academic subject. Knowledge of self and others is typically acquired through natural intuitive routes but difficulties in such routes of acquisition are at the heart of autism. People with autism, therefore, have to learn about themselves and others in an

academic way, so the opportunity to engage in this systematically through psychology can be very beneficial. Natural understanding will always be superior (faster and able to happen without effort and alongside other cognitive tasks), but academic psychological skills may be the best route to increased understanding in people with autism. There may still need to be support in applying these academic skills to real-life understanding of self and others, but it is better than having no way to understand.

Future Directions

Technological aids have enabled more individuals with autism gain and demonstrate their potential. This is likely to continue. Technology itself is likely to grow as an academic subject, and there will be more vocational opportunities to develop and apply such technological academic skills. The fact that typical children now also use more technologically driven and explicit ways of learning means that learning styles of students with autism will begin to merge with those of the typical majority of learners. This should aid the development of inclusive practices in education. People with autism may always remain at a disadvantage when it comes to understanding and operating in the social world, but they may be at an advantage when it comes to understanding and operating in the technological world. As technology takes over many low-level cognitive skills (storing and manipulating data, for example), there will be increased need for the exercise of higher-level academic skills – making sense of the data, problem-solving, and interrogating data in meaningful ways. These are high-level skills but they are teachable, and experience shows that what is clearly (and explicitly) taught can be learnt by people with autism, as long as there are no significant learning or other difficulties.

Already it is seen that some academic skills (such as handwriting) have lost some value as other ways of expressing oneself have developed. There may be other academic skills that become redundant, but it is doubtful if humans can flourish and grow without the exercise of some academic skills. It may be that everyone does not need to

learn how to be a historian, say, but everyone needs to understand about how to find sources, how to make sense of them, and to understand notions of trust and reliability in interpreting data. There will be different ways of teaching such skills, but they will be at least as valuable to children with autism as they will be to all.

Academic Supports

Kara Hume

University of North Carolina, Chapel Hill, NC,
USA

Definition

Academic supports provide students with additional help in specific skill areas or subject areas, such as reading, math, or writing. These may include a small group tutoring session, a test-taking skill program, or other adjustments to the length and difficulty of an assignment, all intended to assist students to reach proficiency in an academic area. Though the term *academic supports* is not used specifically in special education law, it is similar to the term “specially designed instruction,” which is defined in IDEA (Individuals with Disabilities Education Act of 2004) as:

Adapting, as appropriate to the needs of an eligible child...the *content, methodology, or delivery of instruction-*

- i. *To address the unique needs of the child that results from the child's disability; and*
- ii. *To ensure access of the child the general curriculum, so that the child can meet the educational standards within the jurisdiction of the public agency that applies to all children.* [300.39 (b)(3)]

Academic supports can also include accommodations and modifications to a student's scheduling, setting, materials, instruction, and/or student response. *Modifications* change the content that is being taught and/or what is expected of the student, such as providing a text at a different reading level or offering shorter assignments. *Accommodations* change only how the information is received or how the student responds, without altering the content difficulty or student expectations. Accommodations may include providing audiotaped books, allowing answers to be given orally, and using a computer to complete written work. Finally, *supplementary aids* are an additional source of academic support available for students with disabilities, as described in IDEA. These include assistive technology, such as word processors or communication systems; adapted materials, including audio books or highlighted notes; and peer tutors.

Historical Background

Prior to 1975, most individuals with autism spectrum disorders (ASD) in the United States were denied academic instruction in the public schools. These individuals were either not educated or were served in private institutions that focused less on academics and more on the reduction of challenging behavior and/or on the development of life skills (e.g., cooking, cleaning). The passage of the Education for All Handicapped Children Act in 1975 (reauthorized as IDEA in 1990 and including students with autism specifically for the first time) guaranteed for the first time that individuals with ASD and other disabilities could access a free and public education (FAPE). This law also requires that schools and families develop an Individualized Education Program (IEP) which clearly outlines the academic supports (e.g., accommodations, modifications, and supplementary aids) to be provided to the student with ASD. Finally, the law mandates that students with ASD have access to the least restrictive environment (LRE), essentially ensuring that to the maximum extent possible, students with ASD are educated in the general education setting with their nondisabled peers.

Though the law has now been in place for over 30 years, progress in the education of individuals with ASD in the academic domain has been slow. The academic profile of individuals with ASD is complex, and academic skills are often difficult for individuals with ASD to fully demonstrate during assessments and classroom instruction. Historically, most individuals with ASD, as many as 75%, were thought to also have a diagnosis of mental retardation (Ghaziuddin 2000). Due to better instrumentation and understanding of the learning profiles of individuals with ASD, more recent research indicates that approximately 16–30% of the population with ASD has a comorbid condition of mental retardation (now termed “intellectual disability” in the United States) (de Bildt et al. 2004).

Accurately identifying intellectual disabilities in individuals with ASD has been challenging, as has accurately identifying their academic strengths and needs. Individuals with ASD often present an uneven profile of skills, as they may be reading at a very young age (i.e., hyperlexia) but may not be able to describe what they have read or respond verbally to comprehension questions. Similarly, individuals with ASD may have other splinter skills (i.e., a talent or ability in a specific area such as music or calendar knowledge) that may not translate to other areas such as math or reading. Without an accurate understanding of an individual's present level of performance in academic domains, practitioners have had difficulty in developing and implementing appropriate academic supports for students on the autism spectrum.

Current Knowledge

Research in the last decade focused on the cognitive profile of individuals with ASD has informed the field around important and often essential academic supports designed to benefit students with ASD. Following is a brief summary of the processing style of many on the spectrum as well as the state of academic supports currently in use by individuals with ASD. Lastly, a brief description of a number of currently used academic supports will be described.

The Cognitive Profile of Many Individuals with ASD

Auditory and Visual Processing: Research indicates that individuals with ASD may process auditory or linguistic information at a slower rate than their typically developing peers (Cashin and Barker 2009). This auditory processing lag can cause great difficulty during traditional classroom instruction. In addition, research indicates that processing verbal and visual stimuli simultaneously may also be difficult. Visual processing, however, appears to be intact and in fact, can be a strength for individuals on the spectrum.

Weak Central Coherence: Individuals with ASD may have difficulty processing incoming information in context, and instead, the specific details of an event or concept are remembered instead of the “big picture.” This piecemeal processing makes understanding abstract concepts more difficult, as information is stored in chunks without being unified by past experiences or understandings of the world. For example, when recalling a story, individuals with autism are more likely to remember only specific details of the story, perhaps names and locations, rather than the main idea of the story and how it may relate to other stories or past experiences (Hill 2004).

Executive Function: “Executive function” is a term used to describe brain functions such as planning, working memory, and flexibility. These functions are often impaired in individuals with ASD, specifically the ability to plan multi-step sequences of events (e.g., steps required to complete a homework project) and to demonstrate mental flexibility (e.g., shift quickly from one idea or plan to another).

Attention and Inhibition: Individuals with ASD may have difficulty orienting, sustaining, and shifting attention to relevant targets (e.g., the teacher or appropriate topic during instruction) (Patten and Watson 2011). Students with ASD may focus on details that are not relevant, such as a pattern of light created by the blinds or the color of the teacher’s shirt, and miss the most meaningful information or content presented. In addition, individuals with ASD may have difficulty in managing their impulsive behavior (Mesibov et al. 2005).

The State of the Use of Academic Supports

Little is known about what types of academic supports are actually in use by students with ASD, as few researchers have investigated this issue. One source of data, however, has provided the field with a snapshot of the accommodations and modifications used by secondary students with ASD. The National Longitudinal Transition Study 2 (NLTS2) provides data on approximately 1,000 students with ASD ages 14–18 enrolled in secondary education settings. The data indicates that 91% of students with ASD receive some type of academic support or modification in their academic settings (Newman 2007). The types of supports and the percentage of students with ASD who access those supports are listed in Table 1.

Additional learning supports are provided to 81% of the sample (Newman 2007), and those supports are listed below in Table 2.

Finally, 57% of the population used some sort of technology aid to support their academic instruction. See Table 3.

Academic Supports,
Table 1 Accommodations and modifications provided to students with autism

Additional time to complete assignments	52%
More time in taking tests	52%
Alternative tests or assessments	49%
Slower-paced instruction	41%
Shorter or different assignments	38%
Modified tests	33%
Modified grading standards	30%
Tests read to student	25%
Modifications to physical aspects of the classroom	16%

Academic Supports, Table 2 Learning supports provided to students with autism

Monitoring of progress by special education teacher	57%
A teacher’s aide or instructional assistant	55%
More frequent feedback	32%
Learning strategies/study skills assistance	22%
A peer tutor	14%
Self-advocacy training	13%
Tutoring by an adult	9%
A reader or interpreter	6%

Academic Supports, Table 3 Technology aids provided to students with autism

A calculator for activities not allowed other students	28%
Computer software designed for students with disabilities	23%
A computer for activities not allowed other students	16%
Communication aids	16%
Computer hardware adapted for special needs	8%
Books on tape	8%

Description of Commonly Used Academic Supports with Students with ASD

As practitioners gain a better understanding of the cognitive profile of the individuals with ASD that they serve, they are more likely to select meaningful and successful academic supports. Below are some of the most commonly used supports designed to match the academic content and expectations to the strengths and needs of individuals with ASD.

Additional Time: Providing extra time for students with ASD to complete assignments or tests is a common academic support and is recommend for students who have auditory processing lags as described above, as well as for students who may have anxiety, a common co-occurring condition. The time constraints posed by testing protocols may prompt higher levels of anxiety, thus reducing academic success.

Visual Supports: Visuals are a common academic support used by individuals with ASD. Visual supports include any concrete cue that supports verbal explanations and directions provided by teachers. These include diagrams, pictures,

objects to hold, graphic organizers, concept maps, outlines, flowcharts, checklists, and schedules. Descriptions of abstract concepts should include a hands-on and realistic explanation and application, including a visual representation. Students with ASD may benefit from audio recording class lectures and then later transcribing them or using a peer/peer tutor to assist with note-taking. Highlighting text is also a helpful visual support, as students can then clearly “see” what concepts are important. Classroom rules and expectations should also be presented to students with ASD visually to ensure their understanding.

Organizational Supports: Both the instruction and environment should be organized for students with ASD. Assignments should be broken down into clear smaller steps (i.e., task analysis), and those steps may be written or visually represented clearly on a “to-do” list. Feedback and redirection from teachers should be frequent to ensure task completion. Classrooms should be well organized and free of distracters to assist in maintaining the attention of the students with ASD. Establishing a color-coded folder or filing system for the student’s desk or locker may also assist the student in competing and turning in academic assignments.

Computer-Assisted Instruction: Using computers to present academic materials to students with ASD may be beneficial for several reasons, including the increased predictability, frequent feedback and reinforcement, and the limited need for social interaction; another deficit are for students with ASD. Computer-based teaching has been proven to promote achievement in math, spelling, literacy, and problem-solving.

Assistive Technology: Technology can be used as an academic support in a number of other ways including an organizational tool (e.g., using a personal digital assistant to serve as a reminder or provide a to-do list), a teaching tool (e.g., using video to teach a specific academic behavior or skill), a supplement to instruction (e.g., student listens to a book on tape while the class reads it aloud), a communication tool (e.g., a nonverbal student can indicate the correct answer using a communication device), or a basic support (e.g., a calculator).

Strategy Instruction: Learning strategy instruction provides step-by-step processes for students

to follow in classroom settings and situations. For example, individuals with ASD may be taught specific strategies around test-taking, such as how to read instructions, how to respond appropriately (e.g., filling in “bubbles”), and how to reduce anxiety during test-taking. Strategy instruction can also be used to help students with ASD take notes during a lecture, complete large projects such as a term paper, and write an essay. These strategies have been used with students with learning disabilities with great success and have recently been applied to students with ASD (Songlee et al. 2008).

Attention and Motivation Supports: Several supports can contribute to an increased ability to attend to and successfully complete academic tasks. A self-monitoring procedure teaches individuals with ASD to observe their own attending behavior, compare it with predetermined models of behavior (i.e., attending to task), and record if their behavior matches the desired example. Allowing students to choose the sequence in which activities are completed as well as the stimulus used in activities (e.g., choose what color marker to use) is also a proven academic support for students with ASD. Building academic activities around the special interest of a student with ASD can be helpful to increase motivation, as can allowing access to highly preferred materials after the completion of academic work. Finally, pairing nonpreferred academic tasks with preferred academic tasks has been shown to increase task completion as well.

Academic Subject-Specific Supports: The academic supports described above can be applied across academic subjects. Below are supports designed specifically for the following subject areas:

Writing: Writing is often difficult for individuals on the spectrum, likely due to visual-motor and coordination challenges. These may be reduced or alleviated through the use of several supplementary aids such as word processors, voice recognition software, special pencils or grips, or slant boards (Heflin and Alaimo 2007). Teachers may offer reduced writing assignments or allow students to produce outlines rather than lengthier written assignments. Students may also use a note-taker or scribe to assist in reducing the writing load. Beyond the physical difficulties of

writing, the production of written text can be difficult for students with ASD for other reasons, including organizational difficulties and challenges in developing ideas. Academic supports include the use of graphic organizers, planning charts, writing prompts, a word bank, and/or a story grammar map.

Reading: A number of academic supports have been identified to assist in the development of literacy skills. These include several discussed previously, including graphic organizers, multimedia programs, strategy instruction, and highly structured direct instruction (Chiang and Lin 2007). In addition, cooperative groups, one-to-one instruction, interactive books, peer/class-wide tutoring, and flash cards have proven to be effective academic supports in enhancing literacy skills. Reading comprehension can prove especially difficult for students on the spectrum, as broad themes, story meaning, and character motivation may be missed, though recall of specific details and facts may be intact.

Math: Computational skills have generally been a strength for students with ASD; however, difficulty often arises in applying these skills to real tasks or problem-solving (Aspy and Grossman 2007). Academic supports to assist in skill development in this area include the use of practical examples with pictures or diagrams to clarify concepts, the use of visual and tactile cues such as TouchMath, use of graph paper during computation activities to help students organize their problems, increased time to complete math tasks, use of calculators and computer programs, and peer tutoring.

Future Directions

Additional research is needed in the area of academic supports, including a better understanding of what supports are currently in place for elementary-aged students and how effective the supports are in increasing student engagement and academic success. Matching a support with the cognitive strengths and needs of individual students would be most effective, but additional study is required to determine how to accurately assess the academic skills of students with ASD. This is important work, though challenging, as our understanding

of the cognitive profile of students with ASD is changing and evolving as more sophisticated brain research is conducted, including the use of functional MRIs. Additionally, the prevalence of students with ASD appears to be increasing (Kim et al. 2011), which increases the likelihood that all teachers, both special and general education, will be serving students with ASD, thus implementing a number of academic supports. This requires additional staff training, both for in-service and pre-service teachers, as staff must appropriately implement supports determined by the IEP team. Finally, the use of personal and portable technology with individuals with ASD is on the rise (e.g., iPad, iPod, personal digital assistants, communication devices). It is likely that these devices will serve as academic supports for individuals with ASD, as they can provide visual supports (e.g., graphic organizers, video clips), organizational supports (e.g., to-do lists), strategy instruction (e.g., provide step-by-step cues or directions), and motivational supports (e.g., students with ASD are often attracted to the use of technology). Further research on the efficacy of personal technology as an academic support is warranted.

Accuracy of the ADOS-2 in Identifying Autism Among Adults with Complex Psychiatric Conditions, The

Brenna B. Maddox

Penn Center for Mental Health, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA, USA
Psychology Department, Virginia Tech, Blacksburg, VA, USA

Definition

The diagnostic accuracy of the Autism Diagnostic Observation Schedule, Second Edition (ADOS-2; Lord et al. 2012), with adults who present with serious mental illness (e.g., psychosis), chronic mental health problems, and/or multiple comorbid conditions.

Most autistic adults have at least one co-occurring psychiatric condition (e.g., Buck et al. 2014), and overlapping symptoms can make diagnosis difficult. Clinicians need assessment tools that accurately distinguish autism spectrum disorder (ASD) from other psychiatric disorders in adulthood. The ADOS-2 Module 4 is considered a “gold-standard” instrument for collecting standardized and objective information about social communication skills, restricted interests, and repetitive behaviors in adults. It is a widely used, semi-structured assessment tool that allows systematic evaluation of the presence of ASD symptoms. Although the ADOS-2 shows good sensitivity and specificity in university- and lab-based settings (Hus and Lord 2014; Pugliese et al. 2015), it has rarely been studied in community clinics that serve a more psychiatrically impaired population.

In community clinics, ruling out psychosis is likely an important component of an ASD

evaluation. Although distinct in many ways, there are clear areas of symptom overlap between psychosis and ASD (Chisholm et al. 2015; King and Lord 2011). This is particularly true for the negative symptoms of psychosis (e.g., affective flattening, poverty of speech, social withdrawal), which are similar to the core social communication impairments in ASD.

Three studies have shown that Module 4 may not perform well in differentiating between ASD and psychosis. Bastiaansen et al. (2011) found that the ADOS domain and total scores did not significantly differ between autistic adults and adults with schizophrenia using the original algorithm. The Module 4 only correctly classified 74% of cases, with a sensitivity of 61% and specificity of 82%. Using the same sample, de Bildt et al. (2016) applied the revised Module 4 algorithm (Hus and Lord 2014) and also found that the ADOS did not discriminate well between ASD and schizophrenia, with a sensitivity of 61% and specificity of 50%. Bastiaansen et al. (2011), however, found three ADOS items on which autistic adults scored significantly higher than adults with schizophrenia: stereotyped language, quality of social response, and overall quality of rapport. In a separate sample of adults receiving community mental health services ($n = 75$), the ADOS-2 accurately identified all six autistic adults (Maddox et al. 2017). However, there was a high rate of false positives, with a particular limitation in accurately discriminating between ASD and psychosis. All 21 of the false positive cases had a lifetime history of psychosis symptoms. Of the 57 participants with psychosis, 37% exceeded the clinical cut-off score on the ADOS-2. Elevated ADOS-2 scores in the false positive group were driven primarily by high Social Communication domain scores, but not by high Restricted Interests/Repetitive Behaviors domain scores. This finding is likely due to the overlapping nature of the negative symptoms of psychosis and some core ASD symptoms (e.g., flat affect, limited conversation, reduced eye contact).

It is important for clinicians and researchers to remember that prominent social communication difficulties are not specific to ASD, particularly in a clinically complex setting such as community

clinics, where many patients may present with impaired social communication skills. Module 4 of the ADOS-2 provides important information about current social communication skills, restricted interests, and repetitive behaviors. However, the ADOS-2 should be used with caution as a diagnostic instrument with adults, particularly when the differential diagnosis includes the possibility of psychosis.

Haven, CT, USA

Synonyms

ACh; Cholinergic

Definition

Acetylcholine (ACh) is a neurotransmitter critical in an individual's ability to assess their surroundings and respond accordingly. More specifically,

ACh functions to evaluate the potential reward and/or threat in a certain stimuli or environmental change and act on it. With roles in regulating attention, cognitive flexibility, social interactions, and stereotypical behaviors, ACh has been heavily implicated in autism. ASD patients show unusually sized, numbered, and structured neurons in the acetylcholine output centers of the basal forebrain as well as decreased concentrations of choline, a precursor of ACh. Low levels of choline have also been correlated with autism severity. Postmortem studies reveal a reduction of ACh receptor and receptor subunits. At the genetic level, mutations and duplications in genes encoding various ACh receptor subunits have been found in ASD patients. Furthermore, mutagenesis, inhibition, and/or deletion of various ACh receptor subunit-encoding genes as well as lesions in ACh-containing cells leads to autistic-like behaviors in rodents. Many of these disturbances in ACh neurotransmission can have direct consequences on synaptic plasticity, a process key in learning and memory. Finally, apart from its direct consequences, ACh also plays an indirect role in the modulation of the balance between excitatory and inhibitory neurons. Perturbations in this balance are hypothesized to contribute greatly to pathogenesis of autism spectrum disorders. No differences have been reported in choline acetyltransferase, involved in the formation of acetylcholine, or acetylcholinesterase, involved in the degradation of acetylcholine, activity between ASD patients and unaffected individuals.

Achievement Testing

Melissa Maye

Clinical Psychology, University of Massachusetts
Boston, Boston, MA, USA

Definition

Achievement tests are designed to assess an individual's competencies in relation to scholastic material that she/he has been expected to be exposed to in school, home, and community settings (Stetson et al. 2001). Achievement tests are different from intelligence tests. Achievement tests are designed to measure mastery of a specific

subject, or subjects, such as reading ability, number fluency, and scientific knowledge; whereas, intelligence tests are designed to measure both novel problem-solving abilities and stored knowledge (Stedman 2006). Typically, achievement tests are administered in the school setting, as opposed to in mental health clinics (Klin et al. 2005).

Historical Background

Achievement testing has been respected as an accurate tool of academic attainment since 1914 when the Department of Superintendence of the National Education Association officially adopted a favorable view toward educational assessment (Levine 1976), another phrase for achievement testing. Achievement testing was not held in high regard until it was identified as a political tool that both sides, both educators and policymakers, could use to pursue their own interests. However, the origins of achievement testing date back to 1903 when Edward Lee Thorndike and his students developed the Comprehension, Arithmetic, Vocabulary, and Direction following test, better known as the CAVD. Thorndike believed that these four domains were four of the most important dimensions of intellect (Thorndike 1949). In addition to developing four distinct subtests to assess intellect, Thorndike developed scales for the CAVD. While Thorndike was a frontrunner in the development of the achievement test he was primarily interested in measurement of achievement as a utility to establish psychology as a science (Levine 1976).

Achievement tests have come to be critical in the measurement of elementary, middle, and high school students. These tests are used in all states to assess both a student's competency and a school's success. Achievement testing is especially important for high school students hoping to gain entry into college. Lastly, used clinically, achievement tests are administered on a case-by-case basis to identify strengths and weaknesses for academic planning.

The achievement test was revolutionized during the late 1940s and the early 1950s when Henry

Chauncey developed the Census of Abilities. The Census of Abilities was the first test that the Educational Testing Service published, with Chauncey as the first president. Chauncey's goal in creating the first test of achievement was to be able to assess the strengths of every member of society and to utilize these strengths in determining each person's role in society (Lemann 2000). While this ideology would certainly be considered problematic today, the remnants of the Census of Abilities still exist in the form of the Scholastic Aptitude Test, better known as the SAT. The SAT was one of the first standardized tests to assess individual competencies in the subject areas of reading, writing, and math and significantly changed the procedure in which students are selected for admission to university.

Psychologists have been aware of differences between socioeconomic status and race (which are often confounded in the US context), since the beginning of the development of these measures. However, when Alfred Binet determined that significant differences in level of academic functioning existed across different social classes, this information was used to legitimize different educational experiences for different social classes, as opposed to calling to the need for more equitable educational experiences for children across economic background (Levine 1976). Early achievement test findings were also used to discriminate against other marginalized groups such as racial minorities and immigrants deeming them incompetent (Levine 1976).

This pattern of discrimination against lower social classes and marginalized groups continued into the late 1970s, and to some extent still affects minorities and individuals of lower socioeconomic status today. For example, the effects of summer vacation reading recognition regression have been found to be significant among lower-class students, whereas, middle class students saw improvement in this subtest following summer vacations (Cooper et al. 1996).

It has been found that schooling improves achievement and that highly effective schooling raises achievement more. Until recently, achievement testing had been thought to reflect intelligence and the belief was that the influence of

schooling was nonsignificant (Hansen et al. 2004). This new knowledge has many implications for all students, particularly those with some degree of learning difficulty. This new research indicates that quality and fit of schooling could be significant in a child's achievement score.

Current Knowledge

Two types of achievement tests are generally employed: screening for academic delays/deficits and comprehensive tests to characterize profiles of academic achievement functioning. Screening tests are brief and typically contain only one subtest, or a set of questions, for each subject covered. Comprehensive tests utilize more than one subtest for each subject area and generally cover more depth, often in the service of determining appropriate intervention services. Both screening and comprehensive achievement tests routinely assess reading, writing, and mathematics.

Screening tests are generally short and easier to score. This makes them a useful tool to assess whether or not gaps exist within an individual's educational development and prompt whether or not further comprehensive testing may be needed. The Wide Range Achievement Test-4 and the Wechsler Individual Achievement Test-Screener are two commonly used screening tests that have one subtest each of reading, math, and spelling.

Comprehensive tests assess at least three subject areas typically taught in schools, include at least two different subtests from each subject area, and assess both high and lower levels of cognitive ability within each subject area (Stetson et al. 2001). A commonly used comprehensive test is the Wechsler Individual Achievement Test-Comprehensive. A common achievement test used with individuals with an Autism Spectrum Disorder (ASD) is the Woodcock-Johnson III Tests of Achievement. The Woodcock-Johnson III contains 23 different achievement scales or subtests.

In addition to screening and comprehensive achievement tests, there are single-subject versus multiple-subject achievement tests. Single-subject tests include several subtests designed to

explore an individual's competency within one subject area and multiple-subject tests explore several subject areas with one or more subtest (e.g., reading, writing, and mathematics).

Educators and school psychologists often use multiple-subject tests more often than single-subject tests because they assess at least three school subjects and provide preliminary analysis of an individual's overall level of academic achievement. In general, it is recommended that multiple-subject tests be used first in order to assess areas of strengths and weaknesses. Single-subject tests should then be used to further assess an individual's competency in a specific subject area (Stetson et al. 2001).

Single-subject tests allow an assessor to gain a more in-depth understanding of an individual's competency. For example, a single-subject test, such as the Woodcock Reading Mastery Tests – III, includes subtests such as letter identification, word identification, word attack, word comprehension, and passage comprehension. Single-subject tests may be particularly useful in the development of an individualized education plan (IEP) given that they provide detailed information regarding an individual's strengths and weaknesses in a particular subject, thus allowing for a more exact IEP.

Generally, achievement tests are organized with lower-level cognitive tasks first and increase the cognitive difficulty as the task progresses. Achievement tests are organized in this way because the lower the level assessed the less reliable one can predict performance on higher-level skills. Comprehensive tests have several subtests within each subject area and therefore allow several distinct levels of cognition to be assessed, thus allowing a more accurate prediction of achievement. Screener tests, in large part due to only having one subtest per subject, test lower levels of cognition and therefore do not predict achievement as well as comprehensive tests (Stetson et al. 2001).

A note on seasonal norms: achievement tests that include seasonal norms need to be paid close attention to. The difference in standard score of just 1 day can be significant in some tests (Stetson et al. 2001). Additionally, it has been found that

over summer vacation, achievement test scores tend to regress. Of the three core subjects assessed (reading, writing, and mathematics), it was found that math skills seemed to deteriorate the most (Cooper et al. 1996).

When completing achievement testing with an individual who has an ASD, choosing the right achievement test should depend on the specific needs of the individual. For example, some individuals with an ASD struggle with maintaining their attention and should be administered a screening test to maximize concentrated performance (Koegel et al. 1997). Whereas, other individuals with an ASD may be able to focus for long periods of time but may have considerable gaps in knowledge and a more comprehensive test may be the more appropriate choice (Koegel et al. 1997).

Tests that include visual stimuli and that do not require long verbal responses may also be most appropriate for some individuals with ASD. For example, the Peabody Individual Achievement Test – Revised (PIAT-R) touts a multiple choice format that is designed to be easy to use with individuals having severe disabilities. While the simple administration and multiple choice responses certainly make the PIAT-R a desirable choice for testing individuals with severe disability, it should be noted that this test was developed with a typical population and therefore the norms do not address the unique needs of individual special needs populations.

Future Directions

While considerable gains have been made in the development of achievement tests since they were first developed in the early 1900s, it is imperative that research and development of new tests continue to create measures that represent the abilities of all individuals. When considering the development of new measures, it is important to take into consideration the needs of the groups that most often use achievement tests, aside from those used in state and nationwide testing. Additionally, future editions of achievement tests should strive to include norms for different populations. It would be especially useful, given the number of individuals

affected, if norms for the ASD population were provided. These norms would provide helpful insight to providers and parents regarding what is typical and could be expected of children in this population over the course of their development.

Achieving a Better Life Experience Savings Account (ABLE Savings Account, ABLE Account, 529A Savings Plan, and 529A Account)

Annemarie M. Kelly and
Christina N. Marsack-Topolewski
College of Health and Human Services,
Eastern Michigan University,
Ypsilanti, MI, USA

Definition

An Achieving a Better Life Experience account (ABLE account) is a tax-advantaged savings account for qualified individuals with disabilities (often referred to as “accontholders” or “designated beneficiaries”) (Pub. L. No. 113–295 [2014](#)). ABLE accounts allow beneficiaries to save funds without losing their eligibility for state and federal government benefits programs such as Medicare, Medicaid, Social Security, Supplemental Security Income (SSI), and Supplemental Security Disability Income (SSDI). ABLE account funds can be used for a broad range of health, wellness, and living expenses to support the beneficiary. ABLE accounts are sometimes referred to as “529A accounts” or “529A Savings

Plans” because the ABLE Act amends Section 529 of the US Internal Revenue Code.

History of ABLE Accounts

The Stephen Beck Jr. Achieving a Better Life Experience (ABLE) Act was signed into law on December 19, 2014. The US Congress has since amended the original ABLE Act by passing other legislation including the Consolidated Appropriations Act of 2016 and Tax Cuts and Jobs Act of 2017. The Consolidated Appropriations Act allowed qualified beneficiaries to enroll in any ABLE savings program in any state, not just their state of residence (Pub. L. No 114–113 [2016](#)). The Tax Cuts and Jobs Act made three key changes to ABLE account law by: (1) increasing the yearly contribution amounts allowed from accountholders who are employed (subject to IRS rules); (2) allowing a qualified ABLE accountholder to claim a Retirement Savings Contributions Credit (Saver’s Credit); and (3) allowing funds saved in a government-sponsored college tuition savings account (“529 account”) to roll into a ABLE account (Pub. L. No. 115–9 [2017](#)).

Principles of an ABLE Account

An ABLE account can be a useful special needs planning tool for individuals with autism spectrum disorder (ASD) and their caregivers (US Senate Committee on Finance [2014](#)). See Table 1, Four key benefits of an ABLE account. ABLE accounts were first created in the United States under the Stephen Beck, Jr. Achieving a Better Life Experience Act of 2014 (Pub. L. No. 113–295) and are governed by federal law, the laws of the individual states, and Internal Revenue Service (IRS) administrative rules. Under federal law, ABLE account savings are excluded from the accountholder’s income for the tax year (January 1 through December 31). Accountholders will face taxes and penalty fees if they deposit more than the federal gift tax limit into an ABLE account during a tax year (e.g., \$15,000 in 2020 and adjusted

Achieving a Better Life Experience Savings Account (ABLE Savings Account, ABLE Account, 529A Savings Plan, and 529A Account), Table 1 Four key benefits of an ABLE account

Item number	Summary	Benefit description
1	Tax-free savings	Savings in an ABLE account are not considered part of the accountholder’s income for the tax year (January 1 through December 31).
2	Protected eligibility for government benefits	Savings in an ABLE account cannot cause the accountholder to terminate their eligibility for state and federal government benefits programs.
3	Many possible uses for “qualified disability expenses”	ABLE account funds can be used for a broad range of costs that support the beneficiary. Qualified disability expenses include: education, housing, transportation, employment training/support, assistive technology/ services, health, healthcare services not covered by private insurance or government programs, wellness goods/services, financial planning, financial management, legal assistance, funeral/burial costs, and basic living expenses.
4	Tax deduction incentives (for employed accountholders and for account contributors in certain states)	Any person or organization can contribute to an ABLE account. Several state ABLE account programs offer tax deduction incentives to encourage friends, family, and others to contribute funds to ABLE accounts. Certain ABLE account contributions can qualify as tax deductions for ABLE accountholders who are employed.

A

periodically by the IRS to account for inflation). Accountholders who are employed can contribute funds beyond the federal gift tax limit – these amounts depend on the accountholder’s income totals according to IRS rules (US IRS 2020b).

ABLE account savings are designed to supplement the benefits from private healthcare insurance and government healthcare programs. Importantly, ABLE accounts allow beneficiaries to save funds without losing their eligibility for state and federal government benefits programs from Medicare, Medicaid, and the Social Security Administration (SSA). If ABLE accountholders maintain a total account balance of no more than \$100,000, they can continue to receive care and services from their government means-tested benefits without paying additional out-of-pocket costs (US Social Security Administration 2020). ABLE account balances in excess of this threshold are considered “excess resources” and must be spent down before the accountholder can receive additional benefits that are paid for by the government. The ABLE Act specifies that an accountholder’s government benefits “shall

not be terminated, but shall be suspended” if there are excess resources in his or her ABLE account (Pub. L. No. 113–295 2014).

Under current laws, many individuals with serious disabilities do not qualify for ABLE accounts. To enroll in an ABLE account program in any state, individuals must have a qualified disability that occurred before age 26. Provided you satisfy the age requirement, you are automatically eligible to establish an ABLE account if you are a recipient of SSI and/or SSDI benefits. You also can become eligible to open an ABLE account if you can satisfy each of the following criteria: (a) the above-mentioned age requirement, (b) the SSA’s definition and criteria for a disability with significant functional limitations, and (c) receive a letter from a licensed physician that certifies your disability diagnosis.

Any person, for-profit business, or non-profit organization can make a deposit into an ABLE account. Several states offer tax deduction incentives to encourage friends, family, and crowdsourcing initiatives to fund ABLE accounts. Certain ABLE account contributions can qualify as

income tax deductions for ABLE accountholders who are employed (US Internal Revenue Service 2020a).

Each state allows online applications to open an ABLE account. Users can monitor their ABLE savings through their ABLE program's website and make contributions or withdrawals online. A beneficiary's parent, legal guardian, legal conservator, or Power of Attorney agent can assist in creating an ABLE account. Beneficiaries can set up their ABLE accounts directly if they are age 18 or older and have "legally capacity" (Garner 2019). For purposes of entering into any ABLE account contractual agreement, an accountholder's legal capacity is defined as the ability to understand the fundamental benefits, risks, and effect of entering into the agreement (Parker 2016). Individuals do not have legal capacity when a judge rules that they are entirely incapable of managing financial or personal affairs (National Council on Disability 2018). A person who lacks legal capacity is unable to fully safeguard himself or herself against harm to self, wealth, and/or property (see also Kohn et al. 2013 regarding the growing legal and medical field of "supported decision-making").

Qualified Disability Expenses for an ABLE Account

The funds in ABLE accounts can only be spent on expenses that support the accountholder (Morris et al. 2016). Under the guidelines set forth in the federal ABLE Act statute, these are called "qualified disability expenses" (QDE). Federal law defines several wide-ranging categories for QDE as follows:

[A]ny expenses related to the eligible individual's blindness or disability which are made for the benefit of an eligible individual who is the designated beneficiary [accountholder], including the following expenses: education, housing, transportation, employment training and support, assistive technology and personal support services, health, prevention and wellness, financial management and administrative services, legal fees, expenses for oversight and monitoring, funeral and burial expenses, and other expenses... consistent with the purposes of this section [and in support of the accountholder] (Pub. L. No. 113–295).

QDE for ABLE accounts are broadly defined and not tied to medical necessity. This is a stark departure from other federal healthcare spending requirements, such as Medicare's payments for healthcare costs that are "reasonable and medically necessary" for the diagnosis or treatment of illness or injury (Stein and Lipschutz 2019). As a general rule, Medicare and Medicaid spending does not include care that is still considered experimental, investigative, or unproven. In contrast, the only condition for spending on QDE with an ABLE account is that the expense loosely relate back to the accountholder's disability. Best practices for documenting QDE include keeping a Qualified Expenses Withdrawal Log (e.g., Iowa IABLE 2020).

Possible Challenges with an ABLE Account

When either considering or utilizing ABLE accounts, individuals should take care to weigh all potential challenges and benefits (Hershey et al. 2017a). See Table 2, Six key challenges of an ABLE Account. Users must take care to remain informed about each tax year's annual contribution limit (set by the federal gift tax limit and IRS rules) and their maximum account balance limit (which varies according to each state's law). Account contributions that are in excess of annual limits are subject to penalty taxes.

The total account balance limit for an ABLE account is set by individual state programs and modeled after state limits for college tuition savings accounts (also referred to as "529 accounts"). In most states, the total account limit for ABLE savings is \$300,000 or higher. Though individuals cannot deposit a total amount into their ABLE account over time that exceeds their account balance limit, it is impractical for most accountholders to save more than \$100,000 in their ABLE accounts – ABLE accountholders with savings in excess of \$100,000 receive a suspension of their government benefits. In sum, experts recommend that ABLE accountholders keep their balances at \$100,000 or lower at all times to avoid the out-of-pocket costs associated with suspended government benefits.

After an accountholder has passed away, most state governments will claim and collect all of the

Achieving a Better Life Experience Savings Account (ABLE Savings Account, ABLE Account, 529A Savings Plan, and 529A Account), Table 2 Six key challenges of an ABLE account

Item number	Summary	Challenge description
1	Maximum account balance limitations	The total account balance limit for an ABLE account is set by individual state programs and modeled after state limits for college tuition savings accounts (529 accounts). Many states have set the total account limit for ABLE savings at rates of \$300,000 or higher.
2	Annual contribution limitations	Deposits into an ABLE account cannot exceed the threshold of the federal gift tax limit during each tax year (e.g., \$15,000 in 2020). Account contributions that are in excess of federal limits are subject to a penalty tax.
3	Limited free assistance for account management	Most state governments do not provide comprehensive helplines to provide accountholders with meaningful guidance or individualized assistance. Nationwide, state ABLE programs encourage do-it-yourself ABLE account management online. At the same time, all state ABLE contracts strongly encourage ABLE accountholders to manage their finances with a private attorney, financial planner, and/or tax advisor.
4	Remaining funds claimed by the state government after the accountholder has passed away (in most states)	In most states, all funds that remain in an ABLE account after the accountholder's death will be claimed and collected by the state government to recoup expenses paid to the accountholder as government benefits during his or her lifetime.
5	Most beneficial when combined with other special needs planning tools	Finance experts recommend that, if possible, many accountholders should coordinate the spend-down of their ABLE accounts with a special needs trust (SNT) and/or Roth individual retirement account (IRA). As a best practice, accountholders should discuss their ABLE account plans with a special needs planning attorney to ensure all short- and long-term goals for the ABLE account align with the SNT and other legal instruments.
6	Potential for financial loss (depending on the accountholder's investment selections)	ABLE accountholders assume all investment risks as well as responsibility for any federal and state tax consequences related to the account. Depending on the accountholder's investment selections, it is possible to lose all or a portion of the savings in an ABLE account. Accounts with high investment risks can be impacted very negatively by market conditions. As a best practice, accountholders should consult with a special needs financial planner and/or tax advisor before selecting an ABLE account investment structure with high financial risks of loss.

funds that remain in an ABLE account. This process is often referred to as the government's "estate recovery." Under these laws, a state is allowed to recoup expenses that were paid in the form of government benefits to the accountholder during his or her lifetime. Most ABLE accountholders should consider keeping large savings amounts inside a special needs trust

(SNT), a legal instrument which is typically shielded from government collections after the beneficiary's death (Hershey et al. 2017b). Unlike most ABLE accounts, funds protected in an SNT can be transferred to another person or charity organization as part of a beneficiary's estate through a Last Will and Testament (Andersen and Gary 2018).

ABLE accounts are often most advantageous when combined with other special needs planning tools as part of a comprehensive long- and short-term budget plan (Rephan and Groshek 2016). Finance experts recommend that, if possible, many accountholders should coordinate the spend-down of the relatively low funds in their ABLE accounts with spending from higher savings amounts in their SNT (Abbey and Hershey 2016; see also Hershey and Kelly 2019 regarding using a Roth individual retirement account (IRA) as another possible source of funding for special needs planning in coordination with an ABLE account).

ABLE accountholders and their families should be aware that state governments do not provide comprehensive helplines to provide accountholders with meaningful guidance or individualized assistance. All state ABLE contracts strongly encourage ABLE accountholders to manage their finances with a private attorney, financial planner, and/or tax advisor. Hiring professional consultants can be helpful to protect ABLE account users against accidental financial losses – ABLE accountholders assume all financial investment risks related to their accounts.

Helpful Resources for State-by-State Comparisons of ABLE Programs

Qualified individuals can open an account in any state with an active ABLE account program and are not limited to their current state of residency. One of the greatest initial challenges in creating an ABLE account is determining which state ABLE program to utilize. Those who are interested in learning more about ABLE accounts can consult the online resources available from the National Disability Institute's ABLE National Resource Center (ANRC), a leading comprehensive source of independent information about each state's ABLE program. The ANRC website includes two information research functions: a "Search by ABLE Program Features" tool (ABLE National Resource Center 2020a) and a "View All State Programs" tool (ABLE National Resource Center 2020b). These webpages allow individuals to

compare state ABLE program features in several areas, including: debit card availability, estate recovery rules (state government collections of funds after the accountholder's death), and tax deduction options for in-state residents.

Key Considerations When Selecting an ABLE Account Program

There are six key issues to consider when deciding which ABLE program best serves an individual beneficiary's needs:

1. Many state ABLE programs include account fees for the following services: account maintenance, disbursement, account report printing, rollovers, and administration. Will the ABLE program fees in this state unduly burden or otherwise inconvenience the accountholder?
2. What is this state's total account balance limit for ABLE accounts? Moreover, do these limits align with the accountholder's short- and long-term budget goals?
3. Is the ABLE accountholder or those who contribute to an ABLE account eligible for an income tax deduction in this state?
4. Is the accountholder best served by a program that offers a debit or purchasing card to use ABLE account funds? If so, does this state ABLE program offer a card option?
5. State ABLE programs offer allow accountholders to choose between investment options with varying degrees of financial risk. Does this particular state ABLE account program offer the degree of investment risk that most benefits the accountholder?
6. How will the investment-related fees for this particular state ABLE account program impact the beneficiary? Does this state ABLE program have high investment fees that will significantly reduce the ABLE account balance? (Kelly and Hershey 2018).

In addition to the above considerations, accountholders and/or their families should review state ABLE program contracts in detail, ideally with the assistance of a qualified attorney

and/or financial planner. As part of the ABLE enrollment process, each state program asks applicants to perform a thorough review of voluminous contracts and forms. Generally, each state ABLE program requires accountholders – or their designated agents – to sign an account disclosure agreement, which sometimes runs in excess of 100 pages (e.g., Illinois Able 2020). Applicants should be aware that ABLE account program disclosure forms have various titles depending on the state of origin, including – but not limited to – member plan, program disclosure statement, and plan disclosure statement. Some states combine their ABLE disclosures with participation agreement contracts, while others maintain separate documents.

Hiring Legal and/or Financial Professionals as a Recommended Best Practice

Most ABLE savings account program agreements contain links to additional information regarding investment options, strategies, and potential risks of financial losses. Directly or indirectly, a majority of state ABLE programs encourage do-it-yourself account management, while at the same time, explicitly warning individuals against it with legal disclaimers. Consider, for example, the following broad disclaimer which is prominently placed within several state ABLE program websites and contract agreements:

Before investing in any ABLE program, you should consider whether your home state offers an ABLE program that provides its taxpayers with favorable state tax or other benefits that are only available through investment in the home state's ABLE program. You also should consult your financial, tax, or other adviser to learn more about how state-based benefits (or any limitations) would apply to your specific circumstances. You also may wish to directly contact your home state's ABLE program, or any other ABLE program, to learn more about those plans' features, benefits and limitations. Keep in mind that state-based benefits should be one of many appropriately weighted factors to be considered when making an investment decision (e.g. Alaska ABLE Plan: A Member of the National ABLE Alliance 2020)

After reviewing all contract agreements and associated links, it is a recommended best practice for individuals considering an ABLE account to seek personalized, professional guidance (McGee and Ferguson 2017). If feasible, discuss specific legal, investment, and tax situations in detail with a tax advisor, attorney, and/or other financial planner.

Achieving Academic Independence in Middle School-Outpatient (AIMS-O)

Leanne Tamm and Amie Duncan
Cincinnati Children's Hospital Medical Center,
University of Cincinnati College of Medicine,
Cincinnati, OH, USA

Definition

The Achieving Academic Independence in Middle School-Outpatient (AIMS-O) intervention involves teaching academic executive functioning (EF) skills using behavioral management (e.g., reinforcement, behavioral contract, first-then language, etc.) principles to promote increased independence related to academics. Sessions follow a consistent routine of (1) real-world practice review (discussion of previously taught skill and how it was used at home); (2) teaching component (PowerPoint, video clips, hands-on activities, etc.) that focuses on teens and parents learning key

academic EF skills (e.g., creating a homework system, study cards); and (3) in-session practice of the newly taught concepts/strategies (e.g., parents and teens work together to create a behavioral contract/agreement, study cards, etc.) with coaching from the psychologist. Teens are assigned real-world practice tasks each session that are designed to lead to further mastery of newly taught skills through practice at home with support (as needed) from their parents between sessions. Currently, the seven 90-minute AIMS-O sessions include (1) education related to EF, (2) problem solving, (3) behavioral contracting related to use of academic EF skills, (4) organization and time management skills, (5 and 6) study skills including study cards, memory strategies such as acrostics and acronyms, summarizing skills, and graphic organizers, and (7) planning for use of skills in different settings (e.g., school), school collaboration, and teen initiative. AIMS-O is taught by a clinical psychologist and co-facilitator (e.g., clinical psychology graduate student) and is attended by parents and teens. Parents play a critical role as a coach for their teens to support the acquisition and mastery of key academic EF skills at home. AIMS-O is intended for middle school teens with Autism Spectrum Disorders (ASD) without intellectual disability (ID) who are in the general education setting.

Historical Background

Youth with autism spectrum disorders (ASD) frequently experience significant academic problems in a variety of domains (Whitby and Mancil 2009). Although higher cognitive abilities are associated with better academic performance, youth who have ASD without an intellectual disability (i.e., average IQ) may still struggle academically (Keen et al. 2016). Specific academic challenges in high functioning ASD may include writing (e.g., organizing content), reading comprehension (e.g., understanding how individual details contribute to a greater lesson, taking the perspectives of others), and math problem solving (Keen et al. 2016). While some of these academic

struggles stem from key features of ASD (e.g., social-communication deficits, narrowly defined interests, and concrete/literal thinking), they are also strongly linked to deficits in executive functioning (EF) such as organization, time management, prioritization, and initiation (Pennington and Ozonoff 1996).

EF skills are critical for academic success. Students must be able to initiate tasks, perform multistep sequences of events, reflect, reason, plan, and prioritize (e.g., complete different tasks for several subjects on time), sustain performance and complete tasks, be flexible in their thinking (e.g., select the learning strategy appropriate for each context), and monitor their performance (e.g., manage progress and check for mistakes; (Best et al. 2009, 2011; Endedijk et al. 2011; Fisher and Happe 2005). However, 35–70% of teens with ASD without an intellectual disability present with EF deficits (Blijd-Hoogewys et al. 2014; Pennington and Ozonoff 1996) including deficits in planning, flexibility, shifting set, metacognition (awareness of own thought processes), and monitoring their own behavior (Hill 2004). Common challenges include difficulties getting started on tasks, managing distractions, planning for studying, multitasking, keeping materials organized, and prioritizing tasks. Parents of teens with ASD also report difficulties getting their child to start school work independently (Endedijk et al. 2011; Hampshire et al. 2014). As a result, teens with ASD and their parents may struggle to acquire and manage critical academic behaviors (e.g., material organization, tracking assignments, homework completion, effectively studying, and breaking down large assignments) and experience significant homework issues (e.g., misunderstanding assignments) that are associated with EF deficits.

Persistent EF deficits are clear predictors of poor academic performance (Best et al. 2009, 2011; Fisher and Happe 2005) and poor outcomes in ASD (Clark et al. 2010). There is a clear need for interventions targeting academic EF skills, including planning, organization, time management, and study skills, that lead to more successful outcomes in ASD. Yet, according to the National

Research Council and National Autism Center, there are currently no evidence-based interventions targeting academic EF skills for teens with ASD despite similar interventions already existing for children with similar EF deficits (e.g., attention-deficit/hyperactivity disorder or ADHD). More specifically, to date, there are no randomized clinical trials demonstrating the efficacy of EF interventions for middle school teens with ASD.

The majority of research with children with ASD has focused on the younger ages, with less attention to the transition issues and challenges they face as adolescents (Wong et al. 2015). This is problematic since the inclusion of students with disabilities into general education classrooms is a substantiated transition best practice (Schall et al. 2012). In fact, general education placement of students with ASD has increased at a rate faster than all other disability categories (Whitby 2013). Further, as rates of inclusion for middle school students with high functioning ASD increase, teachers and para-educators do not typically have the support and training to implement evidence-based treatment to meet their needs (Kurth and Mastergeorge 2010). Specifically, most individualized education programs (IEPs) for students with high functioning ASD enrolled in inclusive education settings are more likely to focus on academic progress, but little research has been conducted on how to develop environments and utilize strategies and supports to facilitate academic success (Kurth and Mastergeorge 2010). Given the prevalence of EF deficits coexisting through the transition to middle school, it is unsurprising that students with ASD have significant academic problems in middle school (Adreon and Stella 2001; Mullins and Irvin 2000). In fact, during middle school years, the academic performance of teens with high functioning ASD is approximately 2–3 years below their typical peers (Wagner et al. 2003).

Current Knowledge

AIMS-O is currently still in development. Focus groups with parents, teens with ASD, teachers,

and school administrators confirm that an intervention targeting academic EFs is needed for middle school teens with ASD without an ID. Themes that emerged from parent and teen groups (Tamm et al. 2019) include:

1. *Executive Functioning Is a Barrier to Academic Success*: Both parents and teens agreed that the teens had difficulty with remembering to either do assigned homework or turn in completed homework, which then leads to missing assignments and negatively affects grades. Organization was another prominent challenge noted by both teens and parents. Parents also reported that they provide varying levels of support to help their teen stay organized. Most teens required verbal reminders from teachers to complete assignments. Teens and parents reported that difficulties paying attention also affect school performance. Teens related that they have difficulty listening to others, which gets them in trouble at school and at home. Parents agreed that their teens have difficulty listening and focusing, and they must monitor their teens to ensure tasks are completed. When tasks require sustained attention (e.g., listen to a class lecture), teens often become overwhelmed or frustrated and “shut down,” which then leads to poor performance. Parents noted that teens had difficulties with multitasking. If teens were expected to both pay attention and take notes, only one task would be completed. Additionally, teens reported difficulties at school and home related to a lack of inhibition and self-control (e.g., blurting inappropriate things out in class, working on homework when they should be listening to the teacher). Parents reported that teens respond best to established routines such as a specific time to complete homework.
2. *Expectations for Independence and Socialization Make Middle School Particularly Challenging*: Parents reported that middle school is particularly challenging for their teens. As expectations for independence in the school environment increase, teens with ASD struggle due to their difficulties with organization and planning ahead. Teens’ difficulties with

abstract thinking also interfere with academic success in middle school. Once concepts become more obscure and abstract, teens struggle and take a longer time to complete assignments, which may lead to them avoiding similar tasks in the future. Further, limited abstract thinking causes tension between parents and teens. Unlike other teens, parents reported that teens with ASD often fail to understand that grades are important for future achievements. This inability to connect academic performance with future life aspirations may make teens less apt to excel in school.

3. *Teens with ASD Experience Individual Academic Challenges:* Each teen and parent reported that their teen had different academic challenges. While one teen might have difficulties with English, another would not have problems with English but would report problems with math. Across the groups, teens had difficulties with language arts, math, social studies, science, English, and spelling. Similarly, teens and/or their parents reported using a variety of study strategies including web study, teacher resources, repetitive fact review, reading over textbooks and notes, creating flash cards, and online study programs and apps such as Quizlet.
4. *High Need for Parent Involvement:* More than 80% of parents reported helping teens pack their backpacks and stay organized, as well as helping with homework including determining assignments, helping with completion, and closely monitoring homework. More than 60% reported helping with test studying. All teens and parents reported the use of external rewards to motivate teens to complete work and study for tests. Although formal behavioral contracts were not common, parents and teens reported use of verbal contracts that required teens to perform academic tasks prior to receiving some reward.
5. *Challenges with Academic Accommodations:* A major theme for parents was that their teens were not receiving proper academic accommodations in middle school. Parents felt teens were either given too many, too few, or inappropriate accommodations. The majority of

parents also expressed dissatisfaction with the IEP team at their teen's school stating that if their teen had high grades, then s/he would often not receive assistance with EF deficits (e.g., organization, planning, and prioritizing). Parents reported high levels of frustration as the IEP team would often ignore parents' concerns and sometimes refuse to meet with them. As a result, some parents changed their teen's school in order to receive additional academic supports.

6. *Critical Role for Teachers:* Parents and teens reported that the level and quality of teacher support had a significant impact on these teens' academic success. Teens desired additional help and resources from teachers including homework reminders, study tools, and more in-depth explanations of some assignments. Parents reported that teens had more difficulties when teachers had negative attitudes. These attitudes may have developed because not all teachers are equipped to manage teens with ASD, may not understand how EF deficits affect academic performance, and may benefit from learning to promote the skills taught in the group intervention (e.g., organization, problem solving, and study cards). In contrast, parents noted that when teachers were calm, patient, creative, and persistent, teens were more successful. Overall, parents reported a lack of consistent communication with teachers. They expressed disappointment that teachers sometimes ignored their advice about responding to their teen's behavior. Parents felt that open communication among all involved in their child's education (teachers, parents, aides, IEP teams) was necessary for success in middle school. A blend of in-person and electronic communication strategies was preferred.

A small "proof of concept" trial showed that AIMS-O is possible to deliver, results in meaningful improvements, and is acceptable to parents and teens with ASD (Tamm et al. 2019). For example, attendance was excellent across the seven sessions (100%). Parents rated clinically significant improvements for the teen on the

Children's Organizational Skills Scale (Abikoff and Gallagher 2009) and Homework Problem Checklist (Anesko et al. 1987). On consumer satisfaction ratings, parents gave high ratings for the effectiveness of the group, the content of each session, the effectiveness of the PowerPoint slides, worksheets, visuals, and instructors. However, parents gave lower ratings for how well they thought their teen had understood the content. Teens themselves had generally low ratings for how well they understood their challenges with attention and EF, how to use the study strategies, how to use study cards, how to summarize, how to use time management strategies, and how to create an effective homework system and routine. Given that both teens and parents reported difficulties with teen comprehension of content, additional adaptation of AIMS-O is warranted.

Future Directions

With funding support from the National Institutes of Health, work is ongoing to further adapt AIMS-O for use in the outpatient clinical setting. Based on feedback from expert consultants and key stakeholders, the AIMS-O content and teaching approach is being modified and adapted to address core deficits in ASD. Examples of strategies that will be used to enhance the accessibility of concepts include: use of visual supports (e.g., using graphic organizers as a method of summarizing content), a self-assessment to assist in understanding EF strengths and deficits, use of technology (e.g., videos to teach core components, use of apps for studying and summarizing), worksheets combined with multiple choice lists for new concepts, multiple opportunities for repetition and practice, and hands-on activities to increase engagement while building skills. Also, as schools are increasingly turning to technology (e.g., Blackboard, Power School, Google Classroom, DropBox), strategies for organizing electronic content will be critical. Given the themes identified by parents and teens related to school, an adaptation of AIMS-O for administration in the school setting is warranted. Such work is also underway supported by funding from the Institute of Education Sciences.

Acquired Autism

Isabelle Rapin

Neurology and Pediatrics (Neurology), Albert Einstein College of Medicine, Bronx, NY, USA

Synonyms

Autistic regression; Disintegrative disorder; Language/autistic regression; Regressive autism

Definition

Autism (autism spectrum disorders – ASD) typically denotes a static, behaviorally defined, developmental disorder of the immature brain, with identifiable etiologies rare and biologically treatable causes rarer still. Acquired autism implies newly acquired/progressive brain dysfunction, with multiple, mostly undefined, potential causes, presumably affecting similar brain circuitry as developmental ASD. Acquired autism requires prompt neurologic investigation and, in some cases, brain imaging, electrophysiologic, genetic, or other tests to detect potentially medically treatable causes or progressive disease.

Subtypes of acquired autism (discussed in more detailed entries in the encyclopedia):

1. *Language/autistic regression* – Reported by 20–35% of parents, usually between 15 and 30 months. Its causes are unknown because language regression/plateau is rarely studied while in process, especially when its insidious onset is glossed over. It occasionally follows a nonspecific illness or emotional stress. Epilepsy only exceptionally plays a causative role. Regression rarely overlaps acquired epileptic aphasia (Landau-Kleffner syndrome) of preschoolers who all have seizures or epileptiform EEGs, but not autism.
2. *Childhood disintegrative disorder* – Exceptionally rare language/autistic/intellectual but not motor regression of all functions between ages 2 and 10 years following entirely normal earlier development. Its causes are unknown, its prognosis poor, without known medical treatment. It requires thorough neurologic investigation.
3. *Rett syndrome* – Generalized developmental regression in girls, mostly between 6 and 18 months when they cease progressing, head growth stagnates, irritability, hand stereotypies, and a variety of other systemic and neurologic symptoms appear. Severity varies, prognosis is poor. Most are due to mutations of the *MECP2* gene.
4. *Malignant epilepsies of early life* – Infantile spasms with a hypsarrhythmic EEG (West syndrome) in infancy and Lennox-Gastaut syndrome in toddlers with drop and other seizure

types and slow spike waves in the EEG are the most prevalent harbingers of acquired autism with cognitive impairment. They and others have a variety of genetic and acquired etiologies. Prognosis is guarded, but some are medically treatable; so prompt diagnosis is key.

5. *Cerebellar surgery* – Transitory (usually weeks) postoperative mutism with autistic features following removal of midline cerebellar tumors, mostly medulloblastomas.
6. *Psychoses, drug intoxication* – Catatonia may overlap with acquired autism and needs to be diagnosed because treatable. Psychotic depression, mania, and drug intoxication must be considered in unexplained acquired social withdrawal and loss of language and functional skills. Immunizations are not credible causes of autism.
7. *Encephalopathies* – Rarely, acute or chronic infectious, immune, metabolic, or toxic encephalopathies that involve limbic circuitry may result in an acquired autistic state. Diagnosing the causes of encephalopathies is critical because some are treatable, e.g., Hashimoto encephalitis, NMDA receptor limbic encephalitis, herpes simplex, or other infectious encephalitis.

Action Level Imitation

Nicole Slade

Department of Psychology, University of Massachusetts Boston, Boston, MA, USA

Definition

An individual copies, or mimics (Lopes and Santos-Victor 2004), the actions of a model (Nehaniv and Dautenhahn 1998). It is considered a lower form of imitation because it is not necessary for the imitator to process the meaning of the actions. Action level imitations can range from single actions (e.g., sticking out tongue, tapping on a table, making a bunny hop) to a string of actions. The imitation is considered successful when the behavior or set of behaviors is repeated exactly as presented by the model (Nehaniv and Dautenhahn 1998). This kind of imitation is seen in human newborns as well as in nonhuman primates such as chimpanzees and apes (Byrne and Russon 1998).

Action on Objects

Nicole Slade

Department of Psychology, University of
Massachusetts Boston, Boston, MA, USA

Definition

Movement of an object by another object or person. Action on object imitation trials are often used when studying imitation in children and other nonhuman primates (Tomasello et al. 1993). Some research has shown that adult humans use action on objects to stimulate and engage infants in play.

Action Prediction in Autism

Tobias Schuwerk and Markus Paulus

Department Psychology, Ludwig-Maximilians-Universität München, Munich, Germany

Definition

Action prediction is the inherent social cognitive ability to anticipate how another individual's action will unfold over time. Such projections are essential for smooth reciprocal social

interaction and involve the predictions of others' action goals as well as the means they use to achieve their goals. In everyday life, humans constantly coordinate their actions with others. For example, having a cup of coffee at a café involves numerous joint actions, such as ordering the coffee when the waiter is attending, giving the cash and receiving the change, or holding up the cup so that the waiter can refill it with more coffee from the coffeepot. All these actions have to be sensitively attuned in order to successfully enjoy the cup of coffee without dropping money or spilling hot coffee on one's pants.

Eye movements during the observation of another individual's action reveal that, instead of passively following the movement trajectory of this action, humans proactively anticipate the end state as well as the trajectory of an ongoing action (Gredebäck and Falck-Ytter 2015). These gaze patterns are highly similar to eye movements during the performance of one's own actions (Flanagan and Johansson 2003). Developmental psychological research showed that infants in their first year of life already produce such anticipatory eye movements when they observe another's action (Falck-Ytter and von Hofsten 2006).

A substantial body of research suggests that action processing is altered in autism spectrum disorders (ASDs) and that this affects social interaction and communication abilities in individuals with ASD. Recently, it was proposed that impaired action prediction is a key factor that determines social interaction and communication skills in ASD. Yet, theoretical positions and empirical evidence remain controversial. This entry presents current knowledge on if and how action prediction is altered in ASD. Hence, the entry puts emphasis on more recent work on visual action anticipation (often assessed by eye tracking technology) and mentions older work on verbal action prediction only in passing.

Historical Background

Research on action prediction in ASD was mainly framed by two theoretical backgrounds. First, the *theory of mind deficit hypothesis* suggested that

individuals with ASD have difficulties with the prediction of other's actions, because they are impaired in attributing mental states, such as beliefs or desires, to others and themselves (see Frith 2012). This hypothesis is based on the premise that action predictions require the prior representation of another's goal (e.g., the guest at the neighboring table also *wants* a coffee refill) and belief about that goal (e.g., the guest *thinks* that drawing the waiters attention to herself will get her to that goal; cf., Dennett 1989). Thus, if individuals with ASD have difficulties in attributing mental states such as goals and beliefs, they should also be impaired in predicting the corresponding action (e.g., the guest will lift her empty cup of coffee when the waiter passes).

Second, the *broken mirror hypothesis* suggested that the mirror neuron system is dysfunctional in ASD. The mirror neuron system is a network of brain regions that presumably matches observed actions with one's own motor system and thereby enables action imitation and interpretation (Gallese et al. 2004). It was proposed that an ontogenetically early deficit in this neuronal mechanism of mapping another's and one's own actions in ASD leads to impaired imitation, understanding, and prediction of other's actions (Oberman and Ramachandran 2007).

However, mounting evidence is incompatible with both hypotheses. Children and adults with ASD show typical imitation, understanding, and prediction of goal-directed actions in a variety of paradigms (e.g., Cusack et al. 2015; Falck-Ytter 2010; Marsh et al. 2015; Sebanz et al. 2005). On the other hand, studies using different paradigms suggest that in some situations individuals with ASD do have difficulties with accurate action predictions (e.g., von Hofsten et al. 2009; Vivanti et al. 2011). Together, these findings challenge the theory of mind deficit hypothesis and the broken mirror hypothesis because these frameworks cannot fully explain the nuanced characteristics of action prediction in ASD. Consequently, more refined theories that account for impaired and intact aspects of action prediction in ASD are required (Hamilton 2009).

Current Knowledge

Recent years have seen a surge of empirical work on various levels of action processing in ASD, ranging from the detection of biological motion to belief-based action prediction. These findings have in turn driven rapid advance in the development of new theories.

In contrast to previous research (e.g., Blake et al. 2003; Klin and Jones 2008), several recent studies found no group difference between children, adolescents, and adults with ASD and typical participants in cognitive processes that are presumably required for successful action prediction (Cusack et al. 2015; Murphy et al. 2009; Saygin et al. 2010). For example, Cusack et al. (2015) reported intact detection of animacy, detection of biological motion, and discrimination of different types of actions in adolescents with ASD. Thus, deficient precursor mechanisms cannot serve as explanation for altered action prediction in ASD.

Moreover, the prediction of goals and means of a simple "pick-and-place" action was found to be unaffected in 5-year-old children with ASD (Falck-Ytter 2010). The children watched an agent reaching for objects on a table and placing it into a container at the other side of the table. Just as children from the comparison group, 5-year-olds with ASD visually anticipated the end state of these actions, i.e., grasping the corresponding ball and placing it in the container. In contrast, eye movements of children with and without ASD were reactive when the objects were moving self-propelled, i.e., their gaze followed the movement. This suggests that, when observing other agents, children with ASD proactively process the agent's goal and predict according actions.

Yet, action prediction in ASD seems to reach its limits when it becomes necessary to consider another's false beliefs about a certain situation. This was shown in explicit theory of mind tasks testing verbal action predictions (Baron-Cohen et al. 1985), and more recently using implicit theory of mind tasks, eye tracking versions of the classical explicit paradigms. In these implicit tasks, participants are familiarized with an agent's goal to get an object by opening one of two doors. Individuals with and without ASD need only a few

trials to generate predictive eye movements towards the door that is about to be opened. In the subsequent test trial, the agent falsely believes the object would be located behind door A, although it actually is either behind door B or it was removed completely from the scene. To accurately predict the agent's action in this trial (that she will open door A), participants have to take into account that the agent's upcoming action is based on her false belief that the object would still be behind this door. Children and adults with ASD systematically fail to correctly predict this false belief-based action (Schuwerk et al. 2015; Senju et al. 2010). However, it is important to note that, unlike previously thought, individuals with ASD are able to correctly predict the agent's false belief-based action in a variety of explicit theory of mind tasks (Scheeren et al. 2013). One explanation for this finding is that individuals with ASD, especially those with good intellectual and language abilities, develop compensatory strategies to pass these tasks (cf., Livingstone and Happé 2017).

In sum, current mixed and partially inconclusive evidence on intact and impaired aspects of action prediction in ASD speaks against the ideas of a general action prediction deficit in ASD and that single links in the chain of action processing are broken. Individuals with ASD are in principle able to predict other's actions. Rather, the finding that this ability is hampered in some contexts but not in others suggests that computations associated with successful action prediction work less effectively, and/or alternative cognitive routes are taken to get to an accurate action prediction (Livingstone and Happé 2017).

An appealing way to explain these altered cognitive processes that affect action prediction in ASD is offered by the theoretical framework of *hierarchical predictive processing*. In short, this currently prominent theory holds that we do not perceive the world by the unbiased interpretation of the information conveyed by sensory systems. Rather, we have a model of how the world should look like and our brain uses it to actively and optimally predict incoming sensory information. The flow of information is bidirectional: at each level within the postulated cognitive hierarchy, downward driving predictions and upward

transmitted sensory information are compared. The part of sensory input that cannot be explained by the prediction results in a prediction error, which is passed upward so that adjusted and more accurate predictions can be generated. This theory, describing a cognitively very efficient way of making sense of our world, is able to explain cognitive information processing in a variety of domains, ranging from vision to social cognition (Clark 2013).

Related claims have been made in developmental psychology. Ruffman (2014) suggested a reduced ability for learning from statistical information in ASD. Given that action anticipation and social learning might rely on implicit statistical learning (Paulus 2014; Ruffman 2014), such a deficit could account for a variety of problems associated with ASD.

Pellicano and Burr (2012) suggested that these predictions of sensory information are attenuated in ASD. Thus, perception is less biased by prior expectations about sensory information. Assuming that strong expectations help the cognitive system to reduce the complexity of sensory input, attenuated expectations result in an overburdening stream of relatively unfiltered incoming information that has to be processed. This fits well with the clinical observation of sensory sensitivities and repetitive behavior patterns. Within this framework, the latter can be viewed as a way to reduce the need to process unpredictable external information by creating expectable and consistent sensory stimulation.

In the case of action processing, this means that individuals with ASD are affected in the ability to generate action predictions based on prior experience and current observations. This presumably not only affects the control of one's own actions but also the prediction of other people's actions (Sinha et al. 2014). Indeed, individuals with ASD show deficits in motor coordination like action preparation or action planning (Fournier et al. 2010). And also when watching interactions of others, children and adults with ASD are less likely to predict their actions (Chambon et al. 2017; von der Lühé et al. 2016; von Hofsten et al. 2009). This form of interpersonal action prediction is crucial for smooth interactive turn-taking.

Moreover, there is evidence that even very young children with ASD show less anticipation of other's actions. For example, Brisson et al. (2012) retrospectively analyzed home videos of spoon-feeding situations of children around 5 months of age who have been diagnosed with ASD later. In contrast to a control group, they showed less anticipatory mouth opening when the caregiver moved the spoon towards the infant's mouth. Interestingly, typically developing infants who displayed low-anticipation rates, improved rapidly. Although an increase in accurate anticipations was also observed in infants later diagnosed with ASD, they seemed to learn more slowly from experience in such feeding situations.

Also later in life, the ability to exploit past experience to generate action predictions seems to be affected in ASD. For example, adults and 10-year-old children with ASD showed altered action predictions in a task that elicited visual action anticipations of an agent who repeatedly produced one of two possible actions to get to its goal (Schuwerk et al. 2016). The participants with ASD not only showed overall lower rates of action predictions, they also profited less than the respective comparison groups from frequency information. Adults and children from the comparison groups rapidly used the observation that the agent repeatedly acted the same way to predict that, in the same situation, it will produce the same action again. However, participants with ASD showed less improvement in accurate action predictions over time, suggesting that this form of statistical learning is affected in ASD.

In sum, there is growing evidence that the ability to effectively build expectations of another's upcoming actions based on previously observed actions under the same situational constraints is impaired in ASD. This might not affect the anticipation of simple actions with only one plausible outcome (Falck-Ytter 2010), or actions that follow certain rules (e.g., building a tower with colored pieces following the rule "alternate colors"; Vivanti et al. 2011). But, when options for an action become more complex or additional social cues or beliefs are involved, accurate action prediction might become challenging (Senju et al. 2010; Vivanti et al. 2011). It is important to note

that the ability to learn from experience to generate accurate action predictions is not absent in ASD (Chambon et al. 2017; Schuwerk et al. 2015). Yet, it seems that this form of learning from experience works less efficiently in individuals with ASD.

Future Directions

Impaired hierarchical predictive processing is a promising theoretical account, which is able to elucidate a variety of empirical findings on altered action prediction ASD. However, more evidence is needed to firmly conclude that deficient predictive processing is at the core of observed social interaction deficits in ASD. Moreover, it is unclear whether a predictive processing deficit in action prediction sufficiently explains the entire range of symptoms of impaired social interaction and communication. In other words, is navigating the social world challenging for individuals with ASD merely because it is so unpredictable, or do other factors, for example, the motivation to engage with the social world, also play a role (Chevallier et al. 2012)? Further, if it were the case that decelerated learning from experience with past actions underlies altered action processing in ASD, this could be targeted by interventions that, for example, offer additional opportunities to learn from experience, or help to elaborate more explicit and rule-based strategies to predict other's actions. It is up to future research to investigate if these are viable routes to modulate altered action prediction in ASD.

Active-But-Odd Group

Judith Gould

NAS Lorna Wing Centre for Autism, Bromley,
UK

Definition

Active but Odd

Lorna Wing and Judith Gould (1979) put forward the concept of a spectrum of autistic conditions.

As part of the spectrum, they described different manifestations of social interaction. These were aloof, passive, active but odd in their interactions. Since their early work, an additional group has been included referred to as “over formal and stilted in their approach to others.”

The active-but-odd group are those individuals who make spontaneous approaches to others, but in a peculiar, naïve, and one-sided way. These individuals are usually more able and they approach others on their own terms and their behavior is not modified according to the needs, interests, and responses of the person approached. Often the person seeks to indulge their special interest by talking at another person but not for the pleasure of reciprocal social interaction.

Compared with the aloof and passive groups, this group has much longer vocabularies and use their language considerably more but their speech characteristically is repetitive, long winded, often pedantic with peculiar intonations.

As children, many in this group have pretend play but this is usually repetitive, stereotyped, and often copied from others or DVD's/TV. This type of play can be misinterpreted as imaginative play but on careful observation over time the quality is not representational or symbolic but is a repetitive routine. As adults, this group shows a lack of social imagination. They are unable to foresee the consequences in social and practical terms of their own and other people's actions and to act appropriately on that knowledge. They find it difficult to learn from experience so tend to make the same mistakes repeatedly.

In his paper, Asperger described some children with this pattern of social interaction (1944).

It must be emphasized that there are no clear dividing lines between any of these groups. It is possible for one person to change from one type of social interaction to another or may even show different types of social interaction in different environments, with different people, in different states of health and at different ages. However, at any one time describing the type of social interaction is a helpful indicator in understanding the needs and supporting the individual.

Activity-Based Instruction

Howard Goldstein

Human Development and Family Science, The
Ohio State University, Columbus, OH, USA

Definition

Activity-based intervention (ABI) refers to instruction that is embedded within children's and families' daily activities and routines. The instructional strategies vary according to child goals and needs, but the approach emphasizes child-directed contexts for instruction and the use of naturally occurring antecedents and consequences to develop functional skills.

Historical Background

Diane Bricker and Juliann Woods-Cripe (1992) distinguished activity-based intervention from more traditional approaches to early intervention in the early 1990s. Procedurally, ABI is similar to intervention practices that came earlier, such as incidental language teaching (Hart and Risley 1968), environmental language intervention (MacDonald et al. 1974), embedded instruction (Neef et al. 1984), and routine-based intervention (Dunst et al. 1987). ABI emphasizes the role of parents as teachers and how to capitalize on the potential advantages of parents teaching their children with disabilities during daily activities and routines. Likewise, educators can be encouraged to embed instruction into naturally occurring, daily classroom activities. Activity-based intervention has provided a foundation for the development and evaluation of a number of related interventions that go by a number of general names, such as embedded instruction, routine-based intervention, and integrated therapy. Although there has been a recent focus on teaching intervention targets in the context of children's daily routines in the home, there are also studies on embedding instruction in community settings as well as many studies applying ABI in daily classroom activities.

Rationale or Underlying Theory

Activity-based intervention sought to improve on traditional teaching approaches in several ways. First, this approach was viewed as a way to increase the amount of instruction provided to children with disabilities by involving caregivers as teachers in contexts that would fit into everyday activities and routines. The idea was to capitalize on the natural instruction that many caregivers use with their young children and to expand upon the quantity and quality of those teaching opportunities. Second, the focus on using everyday contexts also provided an approach that would lessen the need to program generalization from contrived teaching situations into everyday contexts. This approach sought to take advantage of the child's interest in stimuli consistently present in the natural environment and the naturally occurring reinforcers that accompany interactions around those everyday events. Third, by focusing on everyday activities, early interventionists, educators, and families might more carefully consider what objectives would be most functional for children with disabilities in present and future environments that they would naturally encounter in their everyday lives. Analyzing those natural contexts could provide insight into what typically occurring antecedents might evoke learned skills and what natural consequences might maintain or strengthen their use.

Goals and Objectives

The goal of ABI is to teach functional skills in the context of daily activities. The specific objectives cut across developmental domains, such as communication, social, cognitive, adaptive or self-help, and motor skills.

Treatment Participants

ABI has been applied to a variety of populations of individuals with developmental disabilities. The bulk of literature has come from early intervention with participants ranging from infants to school age children. Applicability to children with

autism is obvious, especially with a focus on social and communication skills, which tend to be domains of weakness typically addressed to promote the socialization of individuals with autism in natural environments.

Treatment Procedures

ABI represents a departure from practices that were clinician-directed and that took place in clinical or contrived settings. ABI embraced the idea of “natural environments” as a concept that means more than a location for service delivery. It also recognizes that learning should occur in intervention contexts that represent families’ typical and valued activities, routines, and events. Because children learn through participating in their everyday activities and meaningful experiences, ABI seeks to take advantage of these activities as intervention settings. By teaching caregivers, parents, and teachers to take advantage of these learning opportunities, intervention can be dispersed throughout the day to enhance learning and generalization for the child. Although daily routines may be similar across families, they vary in how and when they are completed. Daily activities that follow consistent, predictable sequences, that are repeated frequently, and that produce meaningful, reinforcing outcomes are especially useful for teaching functional skills. Functional skills improve the child’s ability to participate more fully and independently in their natural environments. During familiar routines, opportunities for communication, social, or other responses can be rather predictable. Thus, caregivers are often taught how to prompt and reinforce targeted responses using a range of facilitative strategies that seem appropriate for the child and the caregiver. For example, some caregivers might be taught how to wait and look expectantly to prompt a response, while others might be taught to prompt the child to ask for help before the child gets frustrated. Some caregivers may be encouraged to model targeted responses, and others may be encouraged to prompt more elaborated responses from their child. Sometimes the focus is limited to getting the caregiver to implement a facilitative strategy in one daily activity, and

sometimes the focus is on getting the caregiver to generalize the use of facilitative strategies to multiple activities across the day.

Woods et al. (2004), McWilliam (2010a), Dunst (2001), and their colleagues are among the investigators who have outlined taxonomies for describing daily activities. For example, Kashinath and Woods (2007) highlighted four major categories of family routines: (a) play routines (including constructive play, pretend play, physical play, and social games), (b) caregiving routines (including disability-, dressing-, hygiene-, and food-related activities), preacademic routines (including reading, singing, watching electronic media (TV, computer, video), and writing or drawing), and (d) community and home routines (including community errands, home chores, arts, cultural, and recreational activities). Such frameworks can help families identify the activities that might provide ample learning opportunities for functional skill development in their child.

Implementation of ABI has been characterized as child-centered and family-centered. The child-centered approach emphasizes following the child’s lead and being responsive to the child’s interests, desires, and initiations especially in educational settings. The family-centered approach to ABI requires a great deal of sensitivity on the part of early interventionists to follow the family’s lead and to form a productive partnership. It may take some time to develop a relationship with caregivers that is conducive to open information exchange, observation and discussion of teaching and learning opportunities, joint problem-solving around which routine and facilitative strategies will be most effective, and thoughtful selection of functional target behaviors that will have a meaningful effect on the child’s life. The early interventionist must be aware of the varied values, goals, and circumstances in families’ lives that must be navigated for ABI to be successfully implemented with sufficient frequency and accuracy to be effective.

Efficacy Information

Reviews of naturalistic instruction approaches highlight the difficulty in summarizing the

empirical support for ABI and similar interventions (Hepting and Goldstein 1996; Milagros-Santos and Lignugaris-Kraft 1997; Rule et al. 1998). That is, examples of ABI found in the literature differ quite a bit procedurally, even when called the same thing. Nevertheless, there are numerous studies that have found positive effects from implementing ABI to teach a variety of behaviors, e.g., social skills, picture naming, instruction following, and counting (Pretti-Frontczak et al. 2003). The bulk of the studies summarized by Pretti-Frontczak et al. investigated ABI within classroom settings.

Few of the studies compared ABI to other approaches, such as direct instruction interventions. The advantage of ABI is not necessarily seen during skill acquisition. However, better results tend to be seen in the demonstrations of the generalized use of those skills (e.g., Losardo and Bricker 1994). When teaching strategies are not embedded in activities frequently, then progress on children's targeted objectives tends to be diminished. Milagros-Santos and Lignugaris/Kraft (1997) provide an analysis of instructional features that are likely to affect learning of new skills.

ABI also has been investigated in parent training programs (McWilliam 2010b; Woods et al. 2004). For example, Woods et al. taught caregivers to implement teaching strategies within daily routines; their toddlers with developmental disabilities learned communication skills and demonstrated generalization across routines to varying extents. This work was extended to children with autism (Kashinath et al. 2006).

ABI has broad applicability to teaching a variety of skills, using a variety of intervention agents in a variety of natural contexts or activities. Although evidence indicates that ABI approaches can be effective, procedures for selecting functional goals and teaching them effectively in everyday activities are increasingly being developed. Moreover, as these treatment approaches are better refined, comparative studies will be needed to investigate whether ABI is shown to increase generalization and improve functioning in natural environments in comparison to other approaches.

Outcome Measurement

Any IEP goals that are amenable to use in natural environments could serve as outcome measures. ABI promotes the identification of functional goals that enhance the ability of the child to participate in daily activities with more meaningful involvement and independence. Thus, the outcome measures that are targeted and measured cut across developmental domains (e.g., communication, social, cognitive, adaptive or self-help, and motor skills). Most often, the occurrence of the targeted behaviors is captured through observational data collection. Sometimes, the environment is arranged to enhance the opportunities for the behavior of interest to be demonstrated.

Qualifications of Treatment Providers

ABI has been implemented by a variety of individuals, typically with training provided by an early intervention professional. Parents, caregivers, general and special educators, related service personnel, and paraprofessionals have been responsible for implementing ABI.

Acuity

Armando Bertone

McGill University, Montreal, QC, Canada

Definition

Given that detailed or locally oriented perception is a central tenet of visual cognition in autism (Behrmann et al. 2006; Dakin and Frith 2005; Mottron et al. 2006), several studies have systematically assessed the spatial resolution of vision in autism by measuring visual acuity (VA). VA is generally defined as the ability to perceive targets such as optotypes, letters, or numbers of a specific size at a given distance. For example, “normal” Snellen VA, often referred to as 20/20 vision, is a clinical term that reflects a person's ability to recognize a target (i.e., letter E) from 20 ft away when its defining spatial features (i.e., spacing of lines composing an E target) are separated by a visual angle of 1 arc minute.

Several studies have assessed VA in ASD using a variety of clinical screening charts. For the most part, VA has been demonstrated to be unremarkable in ASD when assessed with either the Crowded LogMAR test (Milne et al. 2009), chart and/or computer-based Landolt-C optotype paradigms (de Jonge et al. 2007; Keita et al. 2010; Tavassoli et al. 2011; but see Ashwin, Ashwin, Rhydderch, Howells, and Baron-Cohen (2009) with replies from Bach and Dakin (2009)), or Snellen-type visual charts (Falkmer et al. 2011). These demonstrations of unaffected visual acuity in ASD suggest that detailed or locally oriented visual perception in autism is not of peripheral or ocular origin.

A more direct method of assessing the spatial resolution of the visual system is to measure contrast sensitivity as a function of spatial frequency, thus defining a contrast sensitivity function (CSF) that describes the variation of sensitivity over a range of spatial frequencies (defined by cycles per degree or cpd) from detailed (or high-spatial frequency) to less-detailed (or lower spatial frequency) information. Surprisingly, relatively few direct assessments of contrast sensitivity are available for ASD. de Jonge et al. (2007) assessed contrast sensitivity using the Vistech contrast sensitivity chart, which included spatial frequency gratings of 3, 6, 12, and 18 cpd. Albeit nonsignificant, their ASD group demonstrated increased sensitivity from the mid- to high-spatial frequencies. This trend was consistent with the electrophysiological findings of Jemel et al. (2010), who demonstrated that mid- and high-frequency gratings elicited similar brain responses in their ASD group only (responses segregated in control group), suggesting a response bias toward detailed or high-spatial frequency information. However, in the only published behavioral assessment of contrast sensitivity function (CSF) in ASD to date, Koh, Milne, and Dobkins (2010) demonstrated unremarkable visual acuity, peak spatial frequency, peak contrast sensitivity, and contrast sensitivity at a low-spatial frequency in a small group of participants with ASD.

Adapin

Karthikeyan Ardhanareeswaran
Autism Program, Child Study Center, Yale School of Medicine, New Haven, CT, USA
Program in Neurodevelopment and Regeneration, Yale School of Medicine, New Haven, CT, USA
Department of Molecular, Cellular, and Developmental Biology, Yale University, New Haven, CT, USA

Synonyms

Doxepin; Silenor; Sinequan; Zonalon

Definition

Usually used in the treatment of depression and/or anxiety, Adapin is a member of a class of drugs known as tricyclic antidepressants (TCAs). TCAs work by blocking noradrenaline and serotonin reuptake by presynaptic neurons, resulting in a greater availability and accessibility of these neurotransmitters to the postsynaptic neuron. Long-term administration can result in an increase in sensitivity and number of adrenergic and serotonergic receptors on the postsynaptic neuron. Serotonin is an inhibitory neurotransmitter that is heavily involved in mood and emotion regulation and has been found to be elevated in the whole blood and platelets of ASD patients. However, the use of TCAs in children and adolescents has been fairly limited due to its narrow therapeutic index and high toxicity profile. TCAs have low receptor specificity and, in addition to their reuptake inhibitory effects, exert antagonistic effects on histamine H_2 , serotonin 5-HT_2 , α_1 -adrenergic, and muscarinic acetylcholine receptors. This results in a large array of side effects including, but not limited to, nausea, drowsiness, weakness, dry mouth, changes in appetite or weight gain, constipation, blurred vision, increased sweating, and decreased sexual drive. Evidence for on-target effects and the reduction of autistic symptoms is limited and conflicting. Accordingly, a Cochrane review in 2012 did not recommend the use of tricyclic antidepressants for the treatment of

individuals with autism spectrum disorder. Doxepin has been FDA-approved for the treatment of insomnia.

West Hartford, CT, USA

Synonyms

[Functional life skills](#)

Definition

The American Association on Mental Retardation (AAMR 2002) defines adaptive behavior as “the collection of conceptual, social, and practical skills that have been learned by people in order to function in everyday lives.” Adaptive behavior is best understood as the degree to which individuals are able to function and maintain themselves independently and meet cultural expectations for personal and social responsibility at various ages. As such, adaptive behavior involves the person’s physical skills, cognitive ability, affect, motivation, culture, socioeconomic status, family, and environment. Persons with autism spectrum disorders often demonstrate a discrepancy between intellectual potential and

consistently displayed adaptive skills. Assessing adaptive behavior can include standardized adaptive behavior scales, observation, interview, or review of anecdotal records. Some commonly used ratings include the Vineland Adaptive Behavior Scales, Second Edition; Scales of Independent Behavior – Revised (SIB-R); Adaptive Behavior Assessment System – Second Edition (ABAS-II); and the Battelle Developmental Inventory, Second Edition (BDI-2).

Adaptive Behavior Assessment System, Second Edition

Sarah A. O. Gray and Alice S. Carter
Department of Psychology, University of
Massachusetts Boston, Boston, MA, USA

Synonyms

[ABAS-II](#); [ABAS, Second Edition](#)

Description

The Adaptive Behavior Assessment System is a reliable, valid, and norms-based questionnaire assessment of adaptive behavior, or the personal and social skills necessary for everyday independent living. Because children and adults with autism spectrum disorders often struggle with practical independent functioning and effective interactions with others, the assessment of adaptive behavior is a crucial part of a comprehensive assessment of individuals on the spectrum.

Now in its second edition, the ABAS-II can be used for individuals across the life span, with norm referenced scores available for ages 0–89. Like other assessments of adaptive behavior, this assessment can be used with individuals with autism spectrum disorders to determine how an individual is responding to day-to-day demands compared to others his/her age, to develop treatment and training goals, to determine eligibility

for services and Social Security benefits, and to assess the capability of adults to live independently. The test may also be used to assess adaptive behavior in individuals with other impairments, including intellectual disability, learning difficulties, or ADHD. The test is published by the Psychological Corporation, and the authors are Patti Harrison & Thomas Oakland.

The ABAS-II assesses three general areas of adaptive behavior: Conceptual, Social, and Practical. These domains were selected according to guidelines of the American Association of Intellectual Disabilities. These three domain areas are divided into ten specific adaptive skill areas, organized according to the specifications of the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV), which is published by the American Psychiatric Association and provides standard criteria for the classification of mental disorders. These ten skill areas are Communication (e.g., “speaks clearly”), Community Use (e.g., “finds the restroom in public places”), Functional Academics (e.g., “tells time correctly, using a watch or a clock with hands”), Health and Safety (e.g., “carries scissors safely”), Home or School Living (e.g., “sweeps the floor”), Leisure (e.g., “invites others home for fun activity”), Self-Care (e.g., “washes hands with soap”), Self-Direction (e.g., “controls temper when disagreeing with friends”), Social (e.g., “says ‘please’ when asking for something”), Work (e.g., “performs tasks at work neatly”). The Work skills area is optional. Communication, Functional Academics, and Self-Direction areas are a part of the Conceptual domain; Social and Leisure skill areas are a part of the Social domain; and Self-Care, Home or School Living, Community Use, Health and Safety, and Work are a part of the Practical domain. The Motor skills area is not a part of any domain score.

The ABAS-II is available in a five forms, all which assess the same areas of adaptive functioning. Parents of children aged 5–21 may use a rating form; a new form for parents of children aged 0–5 was developed for the second edition. There is also a teacher rating form for individuals aged 5–21, as well as a teacher/day care form for children aged 2–5 (also new to the second edition). Finally, there is an adult form for individuals

aged 16–89, with which adult individuals can report on their own adaptive behavior. Forms include between 193 and 241 items, and items are rated on a 4-point scale, with 0 = is not able, 1 = never when needed, 2 = sometimes when needed, and 3 = always or almost always when needed. An additional category is “check if you guessed,” which helps examiners determine how much confidence to place in responses.

The questionnaire takes approximately 15–20 min to complete and around 5 min to score. Scoring assistance software can aid with the speed and accuracy.

A limited amount of research with the ABAS-II in individuals with autism confirms patterns of adaptive behavior deficits similar to those observed with other assessments of adaptive behavior. For example, in a sample of 40 individuals with high-functioning autism and 30 typically developing controls, individuals with autism demonstrated lower general adaptive composites, as well as specific deficits in social skills. The general adaptive composite was negatively associated with autism symptomatology (Kenworthy et al. 2010).

Historical Background

The Adaptive Behavior Assessment System, Second Edition, is a revision and a downward extension of an earlier first-edition version of the test by the same authors, the Adaptive Behavior Assessment System, published just 3 years prior in 2000. The update was in response to the 2002 AAMR guidelines that suggested looking within conceptual, social, and practical domains of adaptive behavior. The ABAS-II added domain scores for these three areas.

Whereas the first edition was available only for school-aged children and adults, the ABAS-II has two new Infant/Preschool forms to allow for administration to parents of children aged 0–5.

Psychometric Data

The ABAS-II provides scores based on age-related norms, based on a standardization sample

that drew from the US Census data from 1999 to 2000. Thirty-one age groups were assessed for each form, with at least 100 participants per group. In addition to normative samples, the standardization included 20 clinical samples, including a clinical sample for autism. However, these clinical samples were small and not randomly selected, so no autism-specific norms exist for the ABAS-II.

A General Adaptive Composite, with a mean of 100 and a standard deviation of 15, is yielded as an overall measure of an individual's adaptive skills. In the second edition, domain composite scores, also with means of 100 and a standard deviation of 15, are yielded. Skill area standard scores have a mean of 10 and a standard deviation of 3. Confidence intervals and descriptive classifications are also provided. Finally, for individuals up to 22 years, age-based percentile ranks and age equivalencies are yielded. The GAC has a lowest possible score of 40, and the GAC ceiling for 0–5 is 160, and for adults and children over 8 it is 120. In addition to scaled scores, information about relative strengths and weaknesses by skill area as well as base rates in the standardization sample are provided.

On the school-aged parent and teacher data from the standardization sample, girls scored significantly higher than boys on the General Adaptive Composite, and this gender effect was stronger in teachers; however, gender accounted for only a small amount of variance (.6% and 2.7%). These gender differences are consistent with some other adaptive behavior tests (e.g., the Adaptive Behavior Inventory for Children, which showed similar patterns), though not all measures of adaptive behavior (e.g., the Vineland Adaptive Behavior Scales does not demonstrates sex differences). Effects of race were also observed in the standardization sample, with white children scoring higher than Latino children. Again, an ethnicity main effect has been observed in some but not all other assessments of adaptive behavior. Given that adaptive behavior is defined according to the cultural norms and expectations regarding independent behavior and social functioning, sensitivity to cultural context is a critical part of the sensitive assessment of adaptive behavior.

The ABAS-II has shown very strong reliability. Most skill areas have internal consistency of .90 or higher. In studies examining test-retest reliability over a 2-week period, General Adaptive Composite correlations were near or above .90 for all versions of the ABAS-II.

The test also demonstrates adequate validity. Factor analysis supports both the three-factor model and the GAC factor. The factor model is similar for boys and girls (Wei et al. 2008). Comparisons to other adaptive behavior measures, such as the Vineland, show correlations ranging between .70 and .84, demonstrating concurrent validity. Clinical validity studies have also suggested that the ABAS-II is highly sensitive when differentiating clinical and nonclinical samples. Correlations with the Wechsler Intelligence Scale for Children-Third Edition, the Wechsler Adult Intelligence Scale-Third Edition, and the Wechsler Abbreviated Scale of Intelligence were medium-sized, confirming that intelligence and adaptive functioning are inter-related but distinct constructs. No predictive validity studies are known.

Items were selected from an original pool of 1500 generated items, from which a third to a half were used in standardization sampling.

The test has been criticized for requiring a high level of reading comprehension for some items (seventh grade) and for its relatively low ceiling (120) (Sattler 2002).

Clinical Uses

Adaptive skills generate opportunities for independence and meaningful social interaction. Given that core deficits in social and communication skills are at the heart of a diagnosis of Autism Spectrum Disorder, measurement of the adaptive skills that children and adults are using – and where they may need remediation – is a key component of assessment and treatment planning for individuals with ASDs. Indeed, some conceptualizations of developmental disabilities suggest more emphasis be placed on adaptive skills than on IQ, as adaptive skills are modifiable and capture real-world implementation, whereas intellectual ability does not necessarily capture the skills an individual is *using* in a day-to-day context

(Schalock 1999). Individuals with autism, particularly high-functioning ones, typically have a profile that includes adaptive skill levels that are lower than intelligence levels.

The ABAS-II provides a categorical and age-normed assessment of individuals' adaptive skills, which can be used to guide treatment planning. The ABAS-II can also be used to generate a profile of an individual's adaptive skills, so that areas of relative strength and weakness can be better understood. For example, if an individual is shown to demonstrate deficits in a skill area (e.g., Social), then specific behavioral interventions can be built around the specific deficits documented in testing. Assessing adaptive behaviors across a range of settings (e.g., home and school) can also provide information about the generalization of skills. Moreover, using a measure like the ABAS-II over time can document progress in adaptive skills or capture students' response to intervention, a critical component of special education service planning.

The ABAS-II can also be used to determine eligibility for services, such as Social Security and special education services under the Individuals with Disabilities Education Act. A documented deficit in adaptive behavior is necessary for a diagnosis of intellectual disability, which often co-occurs with ASDs. Investigating profiles of adaptive skill strengths and weaknesses using the ABAS can also be helpful in differential diagnosis, as children and adults on the spectrum tend to have particular adaptive skill deficits in social and communication areas of adaptive skills.

Definition

Adaptive Behavior

The construct of adaptive behavior has been defined by both the American Association on Intellectual and Developmental Disabilities (AAIDD) and the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) as the collection of conceptual, social, and practical skills that are learned and performed by people in their everyday lives. These three domains of adaptive behavior – conceptual, social, and practical skills – have been

consistently identified through factor analytic work on adaptive behavior (Tassé et al. 2012). Conceptual skills refer to language abilities, reading and writing, numbers, time, and money concepts. Social skills include interpersonal skills, friendships, social participation, and social problem-solving. Practical skills encompass self-care, activities of daily living, health and safety, ability to use transportation, etc.

Postschool Outcomes

Researchers have struggled over the years to define what it means for a person with autism to be successful in adulthood (Henninger and Taylor 2013). As adults with autism have increasingly moved out of institutions and into the community, the criteria for positive outcomes have shifted from merely avoiding life in an institution to independently functioning within the community. Three key areas of postschool outcomes are regularly discussed in the literature on disabilities at large, including ASD: postsecondary education, employment, and independent living. In their systematic review of evidence-based predictors of successful postschool outcomes, the National Technical Assistance Center on Transition (NTACT) identified these three areas as the critical outcomes of interest for students with disabilities (Test et al. 2009). Postsecondary education participation is defined as enrollment in any vocational or technical school, 2-year or community college, or 4-year college. Competitive employment – defined as a job at which a majority of the other workers do not have a disability and the person with a disability is earning at least minimum wage – is generally considered the gold standard for employment among young adults with ASD. Residential independence refers to living on one's own or with a roommate, partner, or spouse (i.e., not with caregivers or paid staff, although support from these individuals may be provided). In the literature specific to autism spectrum disorder (ASD), social relationships are often considered another important component of postschool outcomes, including having at least one meaningful friendship with a person in the same age group who is not a paid staff member (Henninger and Taylor 2013).

Historical Background

Transition to Adulthood for Youth with ASD

The transition from secondary school to adulthood is a growing area of concern within the ASD community. In fact, many researchers describe this period of time as a “services cliff” because of the steep decline in services that are available after a student with ASD graduates high school (Roux et al. 2015). It has been well-documented that adults with ASD have poor outcomes compared to their peers without disabilities and peers with other types of disabilities. Data from the National Longitudinal Transition Study-2 (NLTS2) – a large, nationally representative, 10-year longitudinal study of transition-aged youth receiving special education services – is commonly used to summarize the postschool outcomes of youth with ASD and other kinds of disabilities (Newman et al. 2011; Roux et al. 2015). These data show that among young adults with autism ages 23–26, just 44% attended any type of postsecondary education, less than all other disability types except intellectual disability and multiple disabilities. Seventeen percent lived independently, which was lower than all other disability types except multiple disabilities. Twenty-four percent had no socialization with peers, either in person or on a phone call, in the past year, which was lower than all other disabilities studied. Just 63% of the sample with ASD had worked for pay since leaving high school, which was lower than all other disability types except multiple disabilities. Additionally, the majority of people with ASD who had a paid job were working part-time jobs for approximately minimum wage. In many cases, it took 2 years or more to find a job after graduating high school. Findings also show that young adults with ASD have difficulty maintaining a job relative to their peers with other kinds of disabilities. These negative outcomes exist even among adults with ASD who have average or above-average intelligence. Despite average cognitive abilities, they are struggling to engage in typical adult activities. Based on these outcomes, it appears these young adults do not have the skills or supports they need to succeed in their adult lives. Therefore, it is crucial to understand the factors that predict a successful transition.

Adaptive Behavior Profiles in ASD

Research indicates that adaptive skills are likely a key factor in the successful transition to adulthood for youth with ASD. Children and adults with ASD have unique adaptive behavior profiles. It is relatively common for people with ASD to have “scatter” in their skills, meaning that scores on some domains are much higher than others. Research consistently finds that people with ASD have the lowest scores in socialization, as measured by the Vineland Adaptive Behavior Scales (e.g., Kanne et al. 2011). However, some studies have described an “autism profile” in which daily living skills are an area of relative strength, while others find that daily living skills are a relative weakness and communication is the greatest strength. Regardless of the relative strengths and weaknesses found in particular papers, it is important to remember that they are just that: relative. It is well-established that scores on all domains of adaptive behavior for people with ASD are low relative to typically developing peers.

In fact, this pattern of low adaptive behavior scores in people with ASD is a robust finding that exists independent of cognitive functioning. There is a well-documented gap between IQ and adaptive behavior scores in this population. Adaptive functioning often lags behind cognitive level, especially among those with average or above-average IQ (Alvares et al. 2019; Kraper et al. 2017), such that even people with ASD who have high IQ scores often have significantly impaired adaptive behavior. This gap has been shown to emerge as early as 12–36 months of age and widen throughout childhood development and into adolescence (Bradshaw et al. 2019; Kanne et al. 2011; Klin et al. 2007), with gaps as large as 2 standard deviations in some studies (Klin et al. 2007). The gap between IQ and adaptive behavior is largest in people with ASD who are older and who have higher IQs (Kanne et al. 2011). In fact, some studies have found that this gap only exists in those with average intelligence and have found adaptive skills commensurate with mental age in those with intellectual disability (Kanne et al. 2011).

While much of the research on adaptive behavior in ASD has been done on children, some

studies have documented plateaus or declines in adaptive behavior scores through adolescence (Klin et al. 2007; Meyer et al. 2018), where continued improvements are expected. It is important to note that this does not suggest adolescents with ASD are losing adaptive skills, but rather that their rate of progress is slowing down relative to their same-aged peers without ASD. Importantly, age is not associated with either ASD symptom severity or cognitive abilities, so these declines in skill development are found only with regard to adaptive behavior. Therefore, deficits in functional skills are decreasing despite these other two variables remaining the same (Kanne et al. 2011). This trend is worrisome and suggests the need for increased intervention on adaptive skills specifically as children with ASD enter adolescence.

Current Knowledge

In order to improve transition practices and promote positive outcomes for young adults with ASD, it is necessary to understand the factors that influence these outcomes. In the broader disability literature, there is evidence that adaptive behavior skills predict postschool outcomes. For instance, in their systematic review of transition literature across all federal special education disability categories, Test et al. (2009) found that students with more self-care and daily living skills were more likely to participate in all three post-school outcomes of interest: postsecondary education, independent living, and employment. They also found that students with better social skills had improved outcomes in postsecondary education attendance and employment. In a sample of participants with intellectual disability, Dell’Armo and Tassé (2019) found that adaptive behavior variables (social skills, academic performance, and functional skills) were more predictive of postschool outcomes than parent expectations or demographic factors such as race, household income, and parent education level. In a sample with ASD, adaptive behavior – particularly the Daily Living Skills subscale of the Vineland Adaptive Behavior Scales – was most closely correlated with positive adult outcomes

(Farley et al. 2009). Taken together, all of this research suggests that adaptive behavior is likely an important variable in predicting postschool outcomes in ASD, much like in the broader disability population.

Unfortunately, there is relatively little research investigating the effects of adaptive behavior on postschool outcomes. Review papers on predictors of outcomes (e.g., Kirby et al. 2016) have identified relatively few adaptive behavior variables being studied. Much of the research that does exist uses data from the National Longitudinal Transition Study-2 (NLTS). These data are beneficial for studying postschool outcomes as they are longitudinal data that were collected over a period of 10 years. Participants were enrolled in high school at the start of the study and had left high school by the end of the 10 years. Therefore, the data allows researchers to not only describe postschool outcomes but to investigate variables from earlier time points that may be associated with those outcomes. However, a limitation of NLTS2 data is that a standardized adaptive behavior measure was not administered to participants. Therefore, researchers interested in studying adaptive behavior must attempt to use existing variables as a proxy for adaptive behavior (e.g., Dell'Armo and Tassé 2019). Despite this shortcoming, the longitudinal nature of the dataset makes it one of the best available datasets for exploring variables related to postschool outcomes.

Secondary analyses using NLTS2 data have provided further insight into how adaptive behavior predicts postschool outcomes. In a sample of students with autism, Chiang et al. (2012) found that academic performance – which would fall under the conceptual domain of adaptive behavior – was a significant predictor of enrollment in postsecondary education. Similarly, Wei et al. (2013) found that young adults with ASD who had higher levels of basic conceptual skills (i.e., telling time, counting change, reading and understanding signs) were more likely to enroll in postsecondary education.

These same basic conceptual skills, along with conversation ability, have also been associated with social participation outcomes. Orsmond

et al. (2013) found that young adults with ASD who had lower levels of all these skills were less likely to see friends, be called by friends, and be invited to activities (i.e., were more likely to be socially isolated). In terms of employment, Roux et al. (2013) found greater levels of these same basic conceptual skills were associated with greater odds of paid employment, as were greater levels of conversational ability. Another study determined that social skills were a significant predictor of employment after leaving high school (Chiang et al. 2013).

Although studies of adult outcomes do not typically measure psychiatric symptoms, they are important in this population because research suggests that people with ASD experience co-occurring mental health conditions at much greater rates than in the general population (Simonoff et al. 2008). In the only study investigating this topic, Kraper et al. (2017) found that the size of the gap between IQ and adaptive behavior was significantly related to comorbid psychopathology, such that those with greater discrepancies between IQ and adaptive behavior scores were more likely to have another mental health diagnosis like anxiety or depression. While more research is needed to replicate this finding, it appears that adaptive behavior may also impact psychiatric outcomes and psychological well-being.

Future Directions

It should be clear from the information presented that an increased focus on adaptive behavior skills for youth with ASD as they transition to adulthood is warranted. The research that exists on adaptive behavior profiles in this age group suggests that adaptive behavior, and not IQ, is most predictive of postschool outcomes. There are countless examples of young adults with ASD who are of average or above-average intelligence, but adaptive behavior deficits prevent them from living independently, keeping a job, or otherwise succeeding in their adult lives. Future research should put more focus on adaptive behavior for people with ASD in this age group. It would be

useful to know more about typical adaptive behavior profiles (including common areas of relative strength or weakness, as current findings are somewhat conflicting) as well as their longitudinal trajectory (i.e., how do adaptive skills change as youth with ASD age out of school and enter young adulthood?). In addition, these questions should be studied separately in people with ASD who have comorbid ID and those who do not, as prior research suggests that adaptive behavior profiles and outcomes may differ for these two groups.

Despite the importance of adaptive behavior, relatively little work has been done examining the factors that predict or influence adaptive skills (Kraeper et al. 2017). A better understanding of the development of adaptive behavior skills is warranted, with the hope that this would lead to increased knowledge of how to improve adaptive skills in people with ASD. Increased focus should be placed on improving adaptive behavior skills, both in research and in clinical practice. Adaptive behavior skills, in particular those that relate to adult outcomes, should be a target of intervention for all youth with ASD as they transition to adulthood. However, it is still unclear exactly which adaptive skills are most related to adult outcomes. Very little research has specifically investigated how adaptive behavior relates to postschool outcomes, and virtually none of the current research investigating predictors of postschool success use standardized, comprehensive measures of adaptive behavior, as most comes from the same NLTS2 dataset. More research should be conducted to identify which adaptive skills are the most important, as well as develop effective interventions for improving these skills.

Adaptive Behavior Scales

Marisa O'Boyle

Clinical Psychology, University of Massachusetts
Boston, Boston, MA, USA

Definition

Adaptive behavior scales can provide information about children's communication, socialization, and other everyday behavior relative to their age (Demchak and Drinkwater 1998; Gillham et al. 2000). Adaptive behavior scales are different from intelligence tests in that they measure what a child does in the real world versus what a child is capable of in a structured testing situation (Volkmar 2003). The most widely used adaptive behavior scale is the Vineland Adaptive Behavior Scales (Sparrow et al. 1984, 2005); which is a semi-structured interview with parents or caregivers to assess capacities for self-sufficiency in various areas, including communication, daily living, and social, as well as for young children, motor skills.

Historical Background

Beginning with the first descriptions of mental retardation in the 1800s, limits to or an inability to adapt to the demands of everyday life, that is, adaptive behavior, was emphasized as a main descriptor of people considered to have mental retardation (Bothwick-Duffy 2007). Adaptive behavior scales were developed to identify behavior deficits needing treatment in people who were already known to have a disability. Eventually, assessment of adaptive behavior became used for the purposes of diagnosis and eligibility for special services (Bothwick-Duffy 2007). Although social factors are currently viewed as a central defining characteristic of the autistic syndrome, earlier research did not systematically evaluate social dysfunction in autistic individuals; therefore, the utility of a well-standardized, normative

assessment instrument for documenting autistic social dysfunction in terms of daily adaptive functioning became clear (Volkmar et al. 1987).

Literature describing adaptive deficits in autism emerged with Sparrow et al. (1984) and Volkmar et al. (1987) in the 1980s. The assessment of adaptive behavior in individuals with autism along with standardized measures of intellectual functioning was developed to determine whether or not to assign a diagnosis of mental retardation or intellectual disability as well as to distinguish between Autism Spectrum Disorders and other intellectual and developmental disabilities (Carter et al. 1998).

Multiple assessments were created to measure these adaptive skills. The Behavior Inventory for Rating Development (BIRD) was designed to assess types and levels of adaptive behaviors. The BIRD is classified into several subscales of adaptive behavior; Cognitive Development, Self-Help, Physical Development, Social Behavior, and Self-Control (Sparrow and Cicchetti 1984). Other measures of adaptive behavior include the Comprehensive Test of Adaptive Behavior (Adams 1984); Scales of Independent Behavior (Bruinicks et al. 1984); and the Adaptive Behavior Inventory (Brown and Leigh 1986). The more widely used measure, the Vineland Adaptive Behavior Scales-Survey Form evaluates children's personal and social sufficiency in a semi-structured interview with a primary caregiver (Sparrow et al. 1984). This instrument assesses four areas of adaptive behavior: Communication, Daily Living Skills, Socialization, and Motor Skills (Carter et al. 1998; Sparrow et al. 1984).

Current Knowledge

Adaptive skills include whatever capacities an individual possesses to function within their everyday environment, encompassing self-sufficiency as well as social competence (Demchak and Drinkwater 1998; Paul et al. 2004). These skills are particularly important in individuals with autism and related conditions because they contribute the most to an individual's ability to function successfully and

independently in the world (Liss et al. 2001). Adaptive behavior, or children's ability to take care of themselves and get along with others, is an extremely important aspect of multi-dimensional assessment and interventions for preschool and school-aged children as well as for adolescents and adults. Adaptive behavior assessment is useful for diagnosing possible disabilities and developmental problems of preschoolers, which then can lead to planning effective home, family, and school programs (Harrison and Raineri 2007). Given that adaptive behavior is modifiable, it can lead to planning effective home, family, school, community, and vocational planning through the life span.

As noted, the most widely used measurement of adaptive behavior is the Vineland Adaptive Behavior Scales, which are broken down into four scales. The Communication scale refers to skills required for receptive, expressive, and written language; Daily Living Skills scale includes the practical skills needed to take care of oneself and contribute to a household and community; Socialization scale includes skills needed to get along with others, regulate emotions and behavior, as well as skills involved in leisure activities such as play; and finally the Motor Skills scale, comprising both fine and gross motor items, which is typically assessed in individuals below the age of 6 years or when significant difficulty in motor development is suspected. Additionally, the Vineland also contains a Maladaptive Behavior Domain, which assesses the presence of problematic behaviors that interfere with an individual's functioning. The Maladaptive Behavior Domain can be administered to children aged 5 and older and includes both behaviors that are common in early development but are less common as children get older and more serious behaviors that are of concern throughout development (Carter et al. 1998; Sparrow et al. 1984). Further explanation of these scales is as follows: the Communication scale includes expressive, which is what an individual says, while receptive is what an individual understands, and written is what an individual reads and writes. The Daily Living scale includes personal information such as how an individual eats, dresses, and practices personal hygiene, as

well as domestic information such as what household tasks an individual performs, and finally community, such as how an individual uses time, money, the telephone, and job skills. The Socialization scale includes interpersonal information such as how an individual interacts with others, as well as play and leisure, such as how an individual plays and uses leisure time, as well as coping, or how an individual shows responsibility and sensitivity to others (Paul et al. 2004).

Volkmar and colleagues evaluated the ability of the Vineland Adaptive Behavior Scales to diagnose autism by looking at multiple regression equations to predict expected socialization and communication skills on the basis of age, parent education, and sex of the child (Volkmar et al. 1993). While deficits in both communication and socialization are characteristic of the disorder, individuals with autism tend to evidence greater impairment in socialization relative to both communication and daily living skills (Carter et al. 1996). Children with autism display significantly poorer daily living skills and more serious maladaptive behaviors than those with other developmental disorders (Gillham et al. 2000).

Multiple studies have confirmed that the Vineland Adaptive Behavior Scales (Sparrow et al. 1984), is a well-standardized, semi-structured instrument for assessing adaptive behavior. Gillham et al. (2000) reported that autism could be differentiated from both PDD-NOS and non-autistic developmental disorder (DD) with the Socialization and Daily Living scales of the Vineland Adaptive Behavior Scales (Paul et al. 2004; Sparrow et al. 1984). Children with PDD-NOS, when compared with those with autism, differ only in very specific areas, primarily the use of expressive language for communication – particularly syntax and pragmatics – and the areas of adaptive function on which these skills have a direct effect, such as phone use, manners in conversation, and using language to identify and initiate interaction with others (Paul et al. 2004).

Studies have compared the Vineland Adaptive Behavior Scales with other Adaptive Behavior measures and found significant between score correlations (Villa et al. 2010). An international study that compared the Scales of Independent

Behavior (SIB) and the revised Vineland Adaptive Behavior Scales revealed one similar significant factor, demonstrating personal independence for both tests. The summary scores of both tests were found to correlate moderately with IQ as well as with the extent of integration children achieved in their subsequent school placement (Roberts et al. 1993).

There are state and local differences in the adoption of specific criteria for deficits in adaptive behavior. However, the development of instruments that provide national norms such as the Comprehensive Test of Adaptive Behavior (Adams 1984) and Vineland Adaptive Behavior Scales (Sparrow et al. 1984) have enabled more normalized and quantifiable guidelines that could be widely used (Carter et al. 1998).

Adaptive behavior scales have multiple implications for clinical practice, including assessment, diagnosis, and treatment planning. In contrast to intellectual functioning, adaptive behavior is modifiable (Carter et al. 1998). For all individuals, however, cognitive functioning will set some constraints on the level of adaptive functioning that can be achieved. The adaptive behavior scales are a crucial component of a developmental and diagnostic assessment for children with autism and potential comorbid intellectual disability. Additionally, determining strengths and weaknesses in everyday skills has important implications for intervention planning and family support (Perry et al. 2009) and can inform recommendations for educational and psychotherapeutic interventions for high- and low-functioning individuals (Carter et al. 1996). Adaptive behavior scales have been applied to instructional program planning for disabled preschool and school-aged children, adolescents, and adults (Demchak and Drinkwater 1998). Additionally, the assessment of adaptive behavior can be used as an outcome measure to document the efficacy of intervention programs (Carter et al. 1998).

Future Directions

While considerable gains have been made in the development of adaptive behavior scales,

continued research into their generalizability and cultural sensitivity is imperative, as with all measures. The impact of adaptive behavior scales is widely felt, as they are integral to the diagnosis of intellectual disability and have become a key component of assessment and intervention planning for individuals with autism spectrum disorders. Therefore, it is critical that individuals designing intervention programs set attainable goals across domains of adaptive functioning to lead to increased self-efficacy for all involved (Carter et al. 1998). Further research could explore the connections between outcomes of adaptive behavior scales and successful intervention, providing further guidance for practitioners who design these intervention goals. The importance of intensive intervention in the area of adaptive behavior, particularly for children with autism spectrum disorders, remains clear and continued research into successful interventions is necessary.

Description

The ADHD rating scale is an 18-question informant report that screens for symptoms of ADHD in children and teenagers from 5 to 17 years of age (DuPaul et al. 1998, 2016a). This questionnaire has four forms that are separated by setting and age group. There is one form for caregivers (parents and legal guardians) to complete for children (ages 5–10) and another for adolescents (ages 11–17), and there are parallel age forms for teachers. Each question on the ADHD rating scale asks about the presence and frequency of ADHD symptoms. Nine items ask about behaviors related to inattention (“easily distracted”), and nine questions about hyperactive and impulsive behaviors (“interrupts others”). Frequency is rated on a four-point scale from “never” to “sometimes” to “often” to “very often.” The ADHD rating scale, fifth edition, incorporates questions about how these symptoms cause problems at home or school in six areas: (1) getting along with family members/school professionals, (2) getting along with other children, (3) completing or returning homework, (4) performing academically in school, (5) controlling behavior in school, and (6) feeling good about himself/herself. The ADHD rating scale provides symptom counts and percentile scores relative to a community sample of parents

and teachers that were recruited from all regions of the United States.

Historical Background

The ADHD rating scale has been used as an evaluation tool for ADHD for almost 20 years. The ADHD rating scale fourth edition was created with an explicit goal of matching parent and teacher reports of ADHD symptoms to the *Diagnostic and Statistical Manual of Mental Disorders, 4th Edition* (DSM-IV; American Psychiatric Association 1994) and the text revised version (DSM-IV-TR; American Psychiatric Association 2000). While the DSM-IV and DSM-IV-TR prohibited a co-occurring diagnosis of ADHD when a diagnosis of autism spectrum disorder (ASD) was made, scientific papers studied the treatment of ADHD symptoms in ASD (Aman et al. 2008; Handen et al. 2000; Posey et al. 2007; Research Units of Pediatric Psychopharmacology 2005), as well as the influence of ADHD symptoms on the clinical presentation of ASD (Corbett and Constantine 2006; Corbett et al. 2009; Gadow et al. 2006; Yerys et al. 2009, 2011) using the ADHD rating scale and other comparable measures. The ADHD rating scale fifth edition (DuPaul et al. 2016a) integrated additional questions about impairment due to increased recognition that both symptom and symptom-related impairments are critical for making a diagnosis (Power et al. 2015).

Psychometric Data

The ADHD rating scale – fifth edition – has excellent reliability and validity metrics (DuPaul et al. 2016a,b). The normative data for the ADHD rating scale fifth edition was collected on 2079 children from 2079 parents and guardians and 2140 students from 1070 teachers (samples did not overlap). Parent and guardian incomes ranged from <\$5000 to \$175,000 or more per year; 64.1% had White non-Hispanic backgrounds, lived in both metropolitan (86.4%) and non-metropolitan areas (13.6%). Teachers included general (83.3%) and special education (16.4%)

teachers who were predominantly White non-Hispanic (87.3%) and reported a mean of 17.88 years of teaching experience (DuPaul et al. 2016b). The rating scale was shown to have excellent reliability for the inattention and hyperactivity/impulsivity domains across age (alphas >0.89), child's and rater's gender (alphas >0.90), ethnicity (alphas >0.90), and assessment language (English vs. Spanish; alphas >0.88). There was acceptable test-retest reliability over a 6-week period for parent ratings on child and adolescent forms for inattention ($r = 0.80$ and 0.70 , respectively) and hyperactivity/impulsivity ($r = 0.83$ and 0.61 , respectively). Test-retest reliability was also acceptable over a 6-week period for teacher ratings on child and adolescent forms for inattention ($r = 0.91$ and 0.85 , respectively) and hyperactivity/impulsivity ($r = 0.90$ and 0.77 , respectively). The impairment ratings introduced in the fifth edition showed better test-retest reliability for both raters in the child form (correlations range from 0.62 to 0.85) than in adolescents (correlations range from -0.06 to 0.81). Criterion validity was also assessed in comparison to the Connors rating scales (Connors 2008), and validity coefficients were acceptable (correlations ranged from 0.81 to 0.89). The ADHD rating scale – fifth edition – also showed excellent factorial validity with the 2-factor structure (inattention and hyperactivity/impulsivity) being the optimum structure. All critical goodness-of-fit statistics were met (comparative fit index and Tucker-Lewis index > 0.91 and root mean square error of approximation < 0.08). Across both rater groups, the factors were shown to be generally invariant to rater gender, rater age, child gender, and child age, though it should be noted that there was some slight strain on the factor structure within African American male students as well as teacher ratings by age. The delta comparative fit index showed a change equal to or less than 0.002 , which suggests this strain is statistically but not clinically significant. This normative study explicitly excluded children with known neurodevelopmental disorders and cognitive impairments, including autism spectrum disorder (ASD); thus, this sample is highly unlikely to represent the psychometric properties in children and adolescents with ASD.

To date, one study evaluated the psychometric properties of the ADHD rating scale fourth edition in children and adolescents with ASD (Yerys et al. 2017). This study demonstrated strong convergent validity in parent and guardian ratings with an informant report of executive function that includes scales on inhibition (i.e., hyperactivity/impulsivity behaviors) and working memory (inattention, forgetfulness, distractibility behaviors) and showed known age-related changes in symptom severity. However, the ADHD rating scale fourth edition demonstrated weak factorial validity for both rater types, suggesting that several items on the ADHD rating scale may require revision in order to better separate ADHD symptoms in children and adolescents with ASD. A major limitation of this study is that it was conducted with a sample of convenience – families willing to travel to a research center to participate in studies – rather than a community-based sample that matches the demographics of the ASD population in the United States.

Clinical Uses

The ADHD rating scale fifth edition can be used to screen for an ADHD diagnosis. Mental and behavioral health specialists with adequate training in psychological and psychiatric assessment can interpret scores generated from the ADHD rating scale. When used in isolation, the ADHD rating scale fifth edition can be used to identify children at risk for an ADHD diagnosis, but a valid diagnosis of ADHD requires follow-up with either an unstructured or structured developmental and psychiatric interview with caregivers to confirm that the symptoms are not better explained by other diagnoses and are truly impairing the individual's functioning in two settings. Some clinicians may also choose to include continuous performance-based measures, like the Conners' Continuous Performance Test. However, it is important to note that concerns have been raised about the ecological validity of continuous performance tests and that research has shown minor incremental utility of these tests when combined with psychiatric interviews and checklists. While the debate regarding the utility

of continuous performance tests continues (Berger et al. 2017), clinicians continue to rely upon the robust psychometrics of measures like the ADHD rating scale.

Definition

The Individuals with Disabilities Education Act (IDEA) is a federal law that mandates the availability of a free appropriate public education (FAPE) for all eligible children with disabilities. IDEA

defines “disability” as a person “(1) with mental retardation, hearing impairments . . . speech or language impairments, visual impairments . . . serious emotional disturbance . . . orthopedic impairments, autism, traumatic brain injury, other health impairments, or specific learning disabilities . . . (2) who needs special education and related services because of his or her disability or disabilities” (IDEA § 802, emphasis supplied). Thus, children with ASD are eligible for IDEA-related services.

IDEA Part B, Assistance for Education of All Children with Disabilities, mandates educational services for children from ages three 3 to 21. The educational requirements of Part B include an Individualized Education Program (IEP) for each child and demand the placement of each child in the least restrictive environment (LRE) possible.

An “appropriate” education must address a child’s specific educational needs. Determining what is appropriate entails several steps. The responsible state actor must conduct an individualized assessment to ascertain a student’s strengths and weaknesses. Next, an IEP Team, comprising representative of the school district, a teacher, the child’s parents, and if appropriate, the child, must identify appropriate goals and objectives for the student and construct an IEP designed to aid the student in meeting the goals and objectives. Finally, the IEP Team is charged with identifying the aids and services necessary for the child to succeed in the IEP.

States have discretion regarding the title assigned to the IEP Team. The Texas regulatory framework denotes an IEP Team “The Admission, Review, and Dismissal Committee.” Like any IEP Team, and ARD is charged with determining eligibility for special services (“admission”), conducting periodic reviews of IEPs (“review”), and determining the appropriateness of any disciplinary actions (“dismissal”).

IDEA prohibits students from being punished for actions caused by their disabilities. The IEP Team/ARD must review any proposed disciplinary actions to determine whether the targeted behavior was a manifestation of the student’s disability. If the IEP Team/ARD determines that the behavior was not a manifestation of the disability, the school may impose the sanctions that it would

impose for the same behavior committed by a student without disability. Those sanctions may include suspension or expulsion. Because IDEA mandates a free, appropriate, public education, educational services must be offered during the suspension or expulsion.

[Change detection](#)

Definition

Change blindness is a perceptual phenomenon that occurs when a change in a visual stimulus is

introduced and the observer does not notice it (Rensink 2002). A classically used paradigm presents flickering stimuli made of repeated sequences of a picture followed by a “masking” stimulus (e.g., blank screen), which is followed by the initial picture with a change. Our sensory system is able to automatically detect change between pictures when they are immediately contiguous, but detection becomes more effortful when they are separated by a mask for an interval exceeding the temporal limits of visible persistence (Shore et al. 2006). Intervals of more than 100 ms render detection challenging, even when changes are large. Due to the mask, which hinders automatic visual change detection processes, orientation of visual attention is guided by controlled mechanisms that reveal the way we prioritize information that enters working memory (Rensink 2002). Indeed, in such circumstances, we need to attend selectively to the most important items in our environment. The detection of change depends on the degree of interest for the object that changes. Detection of change is more likely for parts of the scene that are of central interest rather than of marginal interest. Thus, change blindness is an indicator of where and to which items and features attention is preferentially directed in the presentation of a visual stimulus. Change blindness is assessed by measuring the time taken before noticing the change and the errors in identifying the change and has been extensively used to investigate change detection in natural visual scenes relevant to real-world experience (Rensink 2002).

Though not a diagnostic feature, attentional atypicalities are often found among individuals with autism spectrum disorder (ASD). The literature is mixed, presenting in some instances superior abilities while in other performances are lower. Studies have shown that individuals with ASD are quicker or more successful than typically developing (TD) control participants at various visual-attentional tasks (for a review, see Kaldy et al. 2016), the overall consensus being that across development and symptom severity individuals with ASD outperform controls on visual search. Change blindness relies on processes that are closely related to those involved in visual

search tasks. It is therefore highly relevant for investigating visual attention in ASD.

Change blindness paradigms have been used to explore visual-attentional abilities in ASD with mixed results. In a number of studies, people with autism showed an enhanced effect of blindness to change, while it was attenuated in others (Ames and Fletcher-Watson 2010). These contradictory findings may stem from the interference of impairments in processing speed when performing tasks that otherwise reveal superior visualization skills in ASD (Hochhauser et al. 2018). In addition, developmental transformations may possibly modulate the balance between executive and perceptive abilities, with recent research suggesting that processing speed impairments affect performances in change blindness even in adolescents (Hochhauser et al. 2018).

Definition

This rare genetic condition is one of a group of disorders termed the leukodystrophies in which myelin (the sheath surrounding nerve cell axons) is damaged. The condition is associated as well with severe damage both to the brain and peripheral nervous system as well as to the adrenal glands. Associated problems can include seizures, movement problems, and loss of function in many areas. Although onset in infancy and adulthood is possible, the onset is usually during childhood, and there may be some confusion early on with other conditions like childhood disintegrative disorder. An adolescent onset type is observed, frequently in males, with more prominent involvement of the spinal cord.

The onset of the condition can be characterized by visual or auditory problems, motor and motor

coordination issues, seizures, and increased behavioral difficulties. Characteristic laboratory findings and MRI findings are observed. A genetic test is available. The prognosis is poor with death after a period of some years of illness. Some dietary interventions are available, and new therapeutic approaches are being investigated.

Definition

Predicting outcome and planning for adult service needs for children with Autism Spectrum Disorders (ASDs) is limited by gaps in current knowledge. The best quality information about autism in adulthood comes from a few population-based longitudinal studies that estimate the full picture of outcomes. However, changes in diagnostic criteria in the 1990s from a comparatively narrow

definition to the broader current criteria for ASD means that studies of adults originally diagnosed as children with historical criteria have limited application to later generations. In addition, longitudinal research that depends on information from aging caregivers has inherent challenges. For example, recall of symptoms from earlier life may be compromised by memory problems and health problems of the aging informant. An alternative research design using cross-sectional samples of adults diagnosed with current, broader criteria can provide data relevant to the future of children being diagnosed today. Such cross-sectional studies are useful adjuncts to population-based, longitudinal research, as they give a more comprehensive understanding of ASD in adulthood and can bring focus to specific issues. For example, the prevalence and variety of behaviors that lead to encounters with law enforcement have been described by Allen et al. (2008).

Two useful prognostic factors for adult outcome in ASD are childhood intellectual ability and onset of communicative speech. Like other people with intellectual disabilities (ID), people with ASD and ID generally achieve a limited range of independence and “success” in adult life as defined in developed Western societies inclusive of gainful employment, a household independent of their parents, and a circle of reciprocal friendships and romantic relationships. Those with average-range intellectual abilities (i.e., ≥ 70) have widely varying adult outcomes. Several longitudinal studies have demonstrated that communicative phrase speech before age 6 and an average-range childhood intelligence quotient (IQ) are necessary for a chance at adult independence but in no way guarantee it (Billstedt et al. 2005; Farley et al. 2009; Howlin et al. 2004; Kobayashi et al. 1992). When assessed in adulthood, barriers to independence in people with ASD and average-range intellectual abilities appear to include co-occurring psychiatric conditions, difficulty with initiation of goal-oriented activities, and poor social skills. There may also be specific genetic variations, developmental processes, educational opportunities, ecological factors, and specialized adult supports that influence levels of independence in adulthood.

Current Knowledge

Natural Course

While ASD is a lifetime diagnosis, several longitudinal studies have shown improvements in autistic symptoms over the life span (Billstedt et al. 2005; Cederlund et al. 2008; Piven et al. 1996; Rumsey et al. 1985; Seltzer et al. 2003). The trend is toward improvement in symptom severity in participants as a group, with the greatest amount of behavioral improvement in individuals who had the highest IQs and the least severe symptom presentation at the initial evaluation. These studies also show that a small proportion of affected individuals no longer meet full diagnostic criteria in adulthood. Importantly, most of these individuals retain subtle impairments that continue to present daily challenges to fully independent functioning.

There also appears to be a small subgroup that experiences significant deterioration in cognitive or behavioral functioning in adolescence (Ballaban-Gil et al. 1996; Eaves and Ho 2008; Kobayashi et al. 1992; Venter et al. 1992). Causes for this deterioration are unknown as yet, but appear unrelated to adolescent seizure-onset that occurs in some individuals with ASD.

Mortality

Studies of mortality in autism have identified a higher rate of mortality for populations with ASD than in the general population, owing largely to complications related to epilepsy and other medical conditions and to accidental deaths that may be associated with ID. Standardized mortality ratios (i.e., the ratio of observed deaths in a specific sample to expected mortality in the general population matched on variables such as age, gender, and length of follow-up period) range from 1.9 to 2.4, approximately twice the expected rate for the general population (Isager et al. 1999; Pickett et al. 2006; Shavelle et al. 2001). Females have had higher mortality rates than males in studied populations, probably associated with a higher rate of ID.

Selected Longitudinal Outcome Studies

A number of authors have categorized outcomes of adults with AD using broad social and

educational or occupational criteria (Howlin et al. 2004). Outcome classifications usually include five nodes and range from Very Poor (i.e., the person cannot function independently in any way) to Very Good (i.e., achieving great independence, having friends and a job). Findings from outcome studies are quite disparate, in spite of considerable similarities between outcome criteria and samples. A consistent finding from published outcome studies is that outcome for a majority (approximately 60%) of individuals with ASD was Fair, Poor, or Very Poor (Billstedt et al. 2005; Eaves and Ho 2008; Farley et al. 2009; Howlin et al. 2004).

Gillberg and Steffenburg (1987) studied outcome for a population-based sample of 23 people with ASD. As children, one-third obtained IQ scores in the mildly mentally retarded range and 26% achieved scores in the normal or near normal ranges. Eight (35%) had communicative speech at age 6. These 23 participants were aged 16–23 years at the time of the follow-up. One person (4% of the sample) obtained a “Good” outcome. Thirty-five percent experienced the “Fair, but restricted outcome.” (i.e., characteristics of “poor” outcome status, but accepted by and included in some social community). Thirteen percent had a “Fair” outcome, and 44% had “Poor” or “Very Poor” outcomes. Childhood IQ and use of communicative speech at age 6 were useful predictors of outcome status. Epileptic seizures were present in one-third of the population, often associated with severe mental retardation and pubertal symptom aggravation.

Kobayashi et al. (1992) conducted a follow-up investigation of 201 adults identified with ASD in childhood through clinical services in Japan. Four of the people had died. The mean age for the remaining 197 young adults was 21 years, 8 months ($S = 3.6$). About one-fourth of the sample had an IQ score of 70 or better at age 6, and about 20% were able to speak without echolalia at that age. An additional 31% used communicative language at age 6 but also used echolalic speech. Forty percent of the sample began school in a general education class, but only 27% remained in general education at the age of 12. At follow-up, 43 (21%) were employed and 11 (6%) were enrolled in higher

education or vocational training programs. Outcome adjustment for 47% was “Good” or “Very Good,” was “Fair” for 32%, and was “Poor” or “Very Poor” for 46%. Childhood IQ was the only strong predictor of outcome in this investigation. Although there were similarities between the sample in this study and others reported, the outcome for these participants was strikingly better, overall. The authors provided some possible explanations including the socio-demographic factors in Japan, advances in public education standards for people with disabilities, intensive intervention histories, and a high proportion of people with ASD and average-range IQ scores at baseline.

Howlin et al. (2004) studied adult outcome for 68 people with ASD who also had a childhood nonverbal IQ score of 50 or better. The mean age at the initial evaluation was 7.24 ($SD = 3.10$) and at follow-up was 29.33 ($SD = 7.97$). Nonverbal IQ scores averaged 80.21 ($SD = 19.28$). At follow-up, the average nonverbal IQ was 75 ($SD = 21.52$). Almost all of the subjects were known to have attended compulsory schooling; however, only 22% left school having achieved formal qualifications. At the time of the follow-up investigation, 23 people were employed. Eight worked in regular, independent jobs; 1 was self-employed as an artist but was unable to earn a living wage; and 14 worked in sheltered or supported employment. Twenty-seven people were occupied in general work/leisure programs at day centers for adults with disabilities. Outcome adjustment ratings for the sample were that 22% had “Good” or “Very Good” outcomes, 19% had “Fair” outcomes, and 58% had “Poor” or “Very Poor” outcomes. Analyses of the assessment results revealed that childhood IQ was a useful predictor of adult adjustment in that those with childhood nonverbal IQ scores of 70 or more were more likely to do well than those with scores below 70. Furthermore, a score of 100 or better did not increase the likelihood that a person would do well in adulthood. For those who were capable of completing a childhood verbal IQ measure, the combination of verbal and nonverbal IQ scores in childhood provided a more precise indication of outcome classification, with scores above 70 in both domains yielding the greatest likelihood of a

“Fair” outcome or better. Specifically, among those with childhood nonverbal IQ scores of 70 or more, 7 had a “Very Good” outcome, 7 had a “Good” outcome, 10 obtained a “Fair” outcome, and 20 had “poor” or “Very Poor” outcomes. Language level at age 5 was useful in predicting overall outcome and residential status but none of the other outcome variables studied demonstrated predictive utility.

Eaves and Ho (2008) followed 48 individuals with ASDs from childhood (mean age = 6.8) to adulthood (mean age = 24) in Canada. Fifty-seven percent of this sample had Autistic Disorder, while the remainder had less severe variants of ASD. Eight of the participants had a childhood IQ score above 70. All participants received special education support during their compulsory schooling years, and 30% engaged in some kind of postsecondary educational program. Overall outcome adjustment ratings were that 21% had “Good” or “Very Good” outcomes, 32% had “fair” outcomes, and 46% had “poor” outcomes. No participants fell within the “Very Poor” outcome categorization. Sixty percent of the sample resided at home with their parents, 19% lived in group homes, and 13% lived in foster care. Almost 80% received a government disability pension and used the services of social workers. In this sample, childhood verbal IQ was most predictive of outcome status. However, the proportion of individuals who were capable of completing an assessment of verbal IQ was not reported.

Also in Cederlund et al. 2008, Cederlund et al. released their study of outcome for 70 adults with autism and 70 adults with Asperger Disorder, after 5 or more years elapsed from original diagnosis. This research team used the same outcome categorization scheme as Gillberg and Steffenburg (1987), with categories of “Good,” “Fair,” “Restricted,” “Poor,” and “Very Poor.” Twenty-seven percent ($n = 19$) of this sample obtained an outcome categorization of “Good,” and 47% ($n = 33$) were categorized as having a “Fair” outcome. Sixteen people, or 23%, obtained “Restricted” outcome status, and two people, or 3%, fell within the “Poor” category. There were no participants with “Very poor” outcome ratings.

Farley et al. (2009) studied 41 adults who had been identified through a population-based study of ASD in Utah in the 1980s. All of these individuals had previous IQ scores of 70 or greater. Mean age at the first assessment was 7.2 years ($SD = 4.1$) and in adulthood was 32.5 years ($SD = 5.7$). Outcome adjustment was somewhat better for this sample than previous samples, with 48% in the “Very Good” and “Good” categories, 34% in the “Fair” category, and 17% in the “Poor” category. No participants fit within the “Very Poor” category of outcome categorization. Six participants did not meet diagnostic criteria for current ASD using gold standard diagnostic procedures, but five of these still retained significant social difficulties reported by themselves or significant others. Half were employed on a full- or part-time basis, and 39% had attended some kind of formal postsecondary education. Over half of the sample (56%) continued to live with their parents, and almost 25% lived in supported living arrangements including a state residential center for people with significant disabilities. Almost 60% of the sample reported co-occurring psychiatric diagnoses. Reported chronic medical conditions were those commonly seen in the general population (e.g., seasonal allergies, gout, high blood pressure).

Cognitive Function

Evidence to date reflects uneven development of cognitive abilities across people with ASD. Initial evaluations during childhood often indicate better nonverbal than verbal abilities. However, many studies show evidence increases in verbal ability and decreases in nonverbal ability during adolescence and adulthood. Group results for individuals with ASD and average-range IQ scores demonstrate consistency in the distribution of subtest scores on Wechsler scales. However, some individuals who have relatively high IQs in childhood demonstrate significant increases in overall ability at follow-up (Gonzales et al. 1993). Disparities among findings may have several causes. Selection of tests at initial evaluation and follow-up for their appropriateness to the research question and participants’ behavior may influence results. Furthermore, tests may not be sufficiently

parallel for comparison, so that some of the variance is attributable to inequality across measures. Variation of tests from the initial evaluation to follow-up further obscures results since within-group variation on measures may be considerable (Howlin et al. 2004). Age at initial IQ also appears to be an important factor, with nonverbal abilities varying more among children initially tested before age 5 (Howlin et al. 2004).

Associated Co-Occurring Conditions

Many of the outcome studies concerning adults with AD provide information concerning co-occurring medical and psychiatric conditions. Few have analyzed the specific contributions these disorders make to restrictions in overall outcome (Danielsson et al. 2005). One of the clearest indicators of the presence of significant co-occurring psychiatric and medical diagnoses is the proportion of individuals who are prescribed anticonvulsant and psychotropic medications. Eaves and Ho (2008) reported that 40% of their sample was prescribed medication for behavioral difficulties. Similarly, 40% of the participants in the population-based study by Billstedt et al. (2005) were prescribed medication for psychiatric disorders, and 40% of the adolescents and adults in another study were prescribed psychotropic medications to control behavior (Ballaban-Gil et al. 1996). Thirty-seven percent of those studied by Farley et al. (2009) were described as taking prescription medications aimed at managing behavioral difficulties.

Epilepsy is a chronic condition involving recurring seizures and is more common in individuals with ASD than in the general population, with an average prevalence rate of 16.8% across epidemiological studies of ASD (Fombonne 1999). This disorder occurs more frequently in individuals with ASD and ID. The onset of seizures typically occurs early in childhood (i.e., before age 2) or in adolescence (Danielsson et al. 2005; Kobayashi et al. 1992). Seizures remit in a fraction of those afflicted (Danielsson et al. 2005). Kobayashi et al. (1992) reported that 19% of their sample, representing the full range of functioning within ASD, had epilepsy, and all took anti-epileptic medication. Nine percent of a sample of

adults with ASD and average-range IQ scores took antiepileptics (Howlin et al. 2004).

Affective disorders challenge a person's capacity to regulate mood and include depression, mania, and bipolar disorder. It is estimated that over 60% of people with AD suffer from a co-occurring affective disorder. In a study of 35 individuals with Asperger syndrome, Ghaziuddin et al. (1998) found that affective disorders were the most common type of psychiatric condition co-occurring in adults, affecting over half of their sample. Figures from outcome studies with adult samples range from 1% to 30% (Billstedt et al. 2005; Farley et al. 2009).

Results of several outcome studies demonstrate that anxiety disorders are present in a large proportion of adults with AD. Rumsey et al. (1985) determined that 50% of their sample was suffering from chronic, generalized anxiety, which they suggested could account for the attention difficulties observed in one-fifth of the sample. Another study of adults with ASD and average-range IQ scores concluded that 40% of their sample had OCD or chronic anxiety (Szatmari et al. 1989). Figures from other outcome studies are much smaller; however, these results may be confounded by the presence of ritualistic characteristics and hyperactivity commonly associated with ASD (Ghaziuddin et al. 1998).

Hyperactivity and short attention span are common in people with ASD. These have been most commonly noted in children, yet some adults present with behavioral characteristics of Attention Deficit-Hyperactivity Disorder (ADHD) as well (Ghaziuddin et al. 1998). Forty (33%) of the adults in the study by Billstedt et al. (2005) presented with hyperactivity.

Psychiatric conditions evident in a small number of people with ASD include tic disorders, psychotic features, and catatonia. Almost 20% of the sample examined by Billstedt et al. (2005) demonstrated tics and 10% of the adults studied by Eaves and Ho (2008) had Tourette's disorder. One of the 15 adults in another investigation presented with Tourette's disorder (Ghaziuddin et al. 1998). A small number of individuals with ASD genuinely have co-occurring psychotic

conditions. Eight percent of the sample in the study of adults with ASD conducted by Billstedt et al. (2005) and 38% of those examined by Szatmari et al. (1989) had characteristics of psychosis. Catatonia is another type of psychiatric disturbance that is rarely observed, but notable in ASD. One of the 15 adults studied by Patricia Howlin et al. (2000) had a sudden-onset catatonic episode during puberty. Billstedt et al. (2005) reported a much higher percentage (12%) in their sample of 120 adults.

While not psychiatric disorders in their own right, maladaptive behaviors are significant deviations from expected behavior for a person's developmental level. They are often disruptive and sometimes dangerous. Maladaptive behaviors are frequently observed in people with ASD of all levels of ability and developmental age. In general terms, maladaptive behaviors have been reported in up to 69% of adults with ASD with no overall difference in frequency between males and females (Ballaban-Gil et al. 1996; Eaves and Ho 2008). Maladaptive behaviors may be relatively infrequent in adults with ASD and average-range IQ scores, but odd or severe enough to preclude acceptance into general social settings over time (Rumsey et al. 1985). Self-injurious behaviors were reported to have occurred in 50% of the sample studied by Billstedt et al. (2005), and have been reported to be more common in females than in males (Ballaban-Gil et al. 1996). Difficulties with toileting and feeding appear to persist in lower functioning individuals, but difficulties with compulsive rituals may develop around these tasks in higher functioning adults as well. Aggression among adults is rarely designed to harm others, but property damage or harm to self may occur intermittently, sometimes in response to unimportant changes or problems in the environment (Rumsey et al. 1985).

Social Relationships

Few adults with ASD develop significant relationships outside of the family of origin in spite of common increases in interest in developing social relationships as individuals with AD age (Rumsey et al. 1985). Almost 75% of family members interviewed in the study by Eaves and Ho (2008)

reported that they enjoyed good to excellent relationships with their affected relative; however, only one-third of the sample of affected adults had one or more friendships outside of the family. Similar results have been found in other studies of adults with ASD (Howlin 2003; Howlin et al. 2004). Females have reportedly experienced greater success with peer relationships than males (Piven et al. 1996). Ten percent of adults in the study by Eaves and Ho (2008) had a romantic relationship at some time in the past, but none of the participants was romantically involved at the time of the investigation. Nineteen percent of the men with Asperger Disorder in the Cederlund et al. (2008) study and 3% of the men with Autistic Disorder were or had been in long-term romantic relationships. Thirty-two percent of those studied by Farley et al. (2009) had dated, and 20% were involved in a serious relationship at the time of the study. In general, very few adults with ASD have been reported to have successful, long-term romantic relationships (Howlin 2003; Howlin et al. 2004).

Education and Employment

Approximately, 15% of adults with ASD studied in outcome research attend postsecondary education programs (Ballaban-Gil et al. 1996; Farley et al. 2009; Kobayashi et al. 1992; Rumsey et al. 1985; Szatmari et al. 1989; Venter et al. 1992). In general, gainful employment for adults with ASD is rare, as is sheltered employment, occupying less than 40% of adults with AD (Howlin 2003; Howlin et al. 2004). While outcome studies of autism into adulthood conducted since 1992 reflect some steady improvements in employment rates, with 22–54% of participants reporting gainful employment on a full- or part-time basis (Ballaban-Gil et al. 1996; Farley et al. 2009; Howlin et al. 2004; Kobayashi et al. 1992; Venter et al. 1992), many of these individuals are underemployed based on their cognitive abilities and academic credentials.

Forensic Problems

Involvement with police officers and other law enforcement agents has been recognized as a major concern for parents of adolescents and

adults with ASD. A study of offending behavior in 33 individuals with Asperger Disorder (Allen et al. 2008) revealed that most engaged in violent or threatening behavior that was related to interpersonal problems including social or sexual rejection, bullying, or family conflict. Investigators have suggested offending behavior in ASD populations was likely to result from coercion by others, misinterpretation of social situations, or obsessional interests, while many with ASD may be protected by their tendency to adhere strictly to rules. Allen et al. (2008) found evidence of this insight in that the least common offenses identified among their population of offenders with Asperger Disorder were drug offenses, theft, fraud, sexual offending, and motor offenses. Cederlund et al. (2008) found that 10% ($n = 7$) of their sample with Asperger Disorder had been involved with law enforcement officers, but the remainder was described as very law-abiding. None of the individuals in their lower functioning sample with autistic disorder had committed legal offenses. In the study by Farley et al. (2009), 29% of the sample was involved with law enforcement officers for infractions after childhood, but these were related exclusively to “suspicious” behaviors deriving from special interests, participants being coerced to engage in antisocial behavior by peers, and social misunderstandings.

Future Directions

The prognosis for a majority of adults with ASD, based on studies conducted to date, is guarded. Future studies are needed to further define the subtypes of ASD, and the factors that influence adult outcome. Studies of genetics, brain imaging, and responses to interventions are likely to yield important information.

Definition

For the purposes of this entry, the transition to adulthood is defined as exiting the secondary school system, resulting in the termination of services received through the school system. High school “exit” is differentiated from “graduation,” as some individuals with Autism Spectrum Disorder (ASD) “graduate” with same-aged peers, but continue to receive secondary school services until age 22. We expect that these youth will be more affected by losing school services than by graduation. Thus, high school “exit” refers to the termination of school-based services.

Historical Background

The transition to adulthood for adolescents without disabilities has traditionally been identified as completing a number of developmental tasks of adulthood. These tasks have been well identified, stemming from Freud’s notion of “love and work” (cited by Hazan and Shaver 1990), and most often include leaving the parental home, finishing school and starting employment, and marrying and having children (Fussell and Furstenberg 2005). In recent years, however, the entry into adulthood for typically developing individuals has become much more ambiguous and prolonged and these markers are often achieved more gradually, and not necessarily in as fixed an order as in the past (Furstenberg et al. 2005). It is increasingly common, for example, for youth to move out of the parental home and into a university residence, but then move back into the parental home for a time after the completion of their

university studies. Additionally, it is often the case that men and women are living independently, have finished their schooling, and are engaged in full-time work activities but have not yet married or had children.

Arnett (2000) proposed the concept of emerging adulthood as a way to account for this heterogeneity in how individuals transition from adolescence to adulthood. The emerging adulthood period, Arnett (2000) explained, is distinct from adolescence and early adulthood because of its relative freedom from social roles and societal expectations. He suggested that the transition to adulthood is no longer best represented by demographic transitions, such as ending formal schooling, getting married, or having children. Instead, the criteria for the transition to adulthood are individualistic, encompassing concepts such as independence in decision making, being responsible for one’s own person, and financial independence (Arnett 2000).

When the adolescent in transition has ASD, the complexity implicit in defining the transition to adulthood is multiplied. Some developmental tasks of adulthood are obtained by most individuals with ASD, such as exiting school. Other tasks, such as moving out of the parental home or finding regular employment, are only achieved by a fraction of individuals with ASD, but these milestones can be modified to be attainable by many more (e.g., structured or semi-structured living arrangements, supported employment). Finally, some tasks are attained by few individuals with ASD, such as getting married or having children. The criteria proposed by the emerging adulthood literature are similarly complicated; many individuals with ASD may never have complete independence in decision making nor have financial independence from both their families and federal or state agencies.

Because of these difficulties in definition, many researchers have forgone theory-based ideas of transition and instead defined the transition period for those with intellectual and developmental disabilities using specific ages (such as ages 18–26 in Blacher 2001). Alternatively, our research has chosen high school exit as a key indicator of the transition to adulthood for two

reasons: (1) of all developmental tasks of adulthood, it is the most commonly attained by individuals with ASD; and (2) nearly all transition studies on individuals with intellectual and developmental disabilities (not ASD) center around high school exit.

In contrast to typically developing adolescents in the USA – who exit high school at a prescribed time (at the end of twelfth grade) – considerable variability exists in the age at which adolescents and young adults with ASD exit the school system. Some exit with their same-aged, nondisabled peers, while others take advantage of the Individuals with Disabilities Education Act (IDEA) and remain in secondary school until their 22nd birthday. Although it may be simplistic to only consider high school exit as a marker of the transition to adulthood, this milestone provides a focused lens through which to examine the research related to the transition to adulthood for people with ASD.

Although few studies have focused on high school exit for youth with ASD, there is considerable research among adults with ASD suggesting that they have difficulties integrating into adult society. Adults with ASD tend to live fairly dependent lives, are underemployed, with those who have employment often holding jobs that do not provide a living wage (for a review see Howlin 2005). The transition out of high school for youth with ASD (and other disabilities) has long been recognized by professionals and policy makers as an important turning point that sets the stage for later adult outcomes. Perhaps the greatest evidence of this is the existence of federal legislation mandating specific requirements for transition planning for youth with disabilities, found in the IDEA of 1997 and the Individuals with Disabilities Education Improvement Act (IDEIA) of 2004. These legislative landmarks mandate that a transition plan must be included in the Individualized Education Plan when a student is 16 years of age (although planning can start sooner) which facilitates “real-world” outcomes by focusing on improvement in education (postsecondary, vocational skills), adult services, independent living skills, and community participation. Furthermore, measurable goals must be

developed that take into account the student’s needs, strengths, interests, and preferences.

By examining the corpus of research on the transition to adulthood, it is clear that autism researchers have lagged behind policy makers and practitioners in recognizing the importance of this transition for youth with ASD. The few existing studies are summarized below.

Current Knowledge

The transition to adulthood is associated with a slowing of improvement of the autism behavioral phenotype. (Taylor and Seltzer 2010) examined change over nearly 10 years in autism symptoms and behavior problems for a community sample of over 240 youth with ASD. The vast majority of these youth exited high school over the study period, allowing us to test changes in symptoms and behaviors while youth were in high school, as well as whether leaving high school impacted that change. We found that all subscales of symptoms and behaviors were significantly improving while youth were in high school and that, in general, improvement significantly slowed down after youth with ASD exited the secondary school system. Although youth with ASD who did not have an intellectual disability (ID) had less severe symptoms and behavior problems than those who had ID as well as ASD throughout the study period, the slowing of improvement following high school exit was more pronounced for youth with ASD who did *not* have ID, relative to those who had a comorbid ID. Furthermore, youth with ASD whose families had lower incomes were more negatively impacted by high school exit relative to youth whose families had higher incomes.

Similar patterns were observed in follow-up analyses (Taylor and Seltzer 2011a), which examined the impact of exiting high school on changes in the mother-child relationship over a 7-year period. We found improvements in three indices of the mother-child relationship – mother-child positive affect, subjective burden, and warmth – while youth with ASD were in high school. After high school exit, however, that improvement stopped – even after controlling for concurrent

slowing of improvement in behavior problems. Once again, whether the youth with ASD had a comorbid ID significantly predicted change in maternal warmth; those without an ID were more negatively affected by high school exit relative to those with a comorbid ID. Further, the number of needed services that were currently not being received also predicted change in the mother-child relationship. There was greater slowing of improvement in mother-child positive affect for youth who had more unmet service needs, relative to those who had fewer unmet needs. In sum, these studies provide evidence of a disruption in phenotypic improvement and parent-child relations in the years following high school exit for youth with ASD.

Youth with ASD without an ID might be more negatively impacted by exiting high school because they have a difficult time finding appropriate vocational or educational activities. This hypothesis was supported in a study by (Taylor and Seltzer 2011b), who examined the post-secondary educational and vocational activities of young adults with ASD who had exited high school an average of 2 years previous to data collection. We found that nearly 25% of the young adults who had ASD without ID had no or minimal vocational/educational activities, and those without ID were three times more likely to have no day activities than youths with ASD who also had comorbid ID. This divergent pattern likely does not represent a lack of abilities on the part of the youth with ASD, but instead the inadequacy of the current service system to accommodate the needs of youth with ASD who do not have ID as they are transitioning to adulthood. Indeed, in this sample, only 18% of young adults without ID were getting some sort of employment or vocational services (e.g., supported employment, sheltered workshop) compared to 86% of young adults with ID. Thus, the lack of appropriate services and limited options for educational/vocational activities for youth with ASD without ID after high school exit may be responsible for the slowing of improvement observed during this time. Youth with ASD and a comorbid ID may be less affected as they more easily fit into the existing adult disability service system.

Limited services and opportunities after high school exit might also play a role in the greater negative impact of high school exit on youth with ASD whose families have lower incomes, relative to those whose families have higher income. A recent study by Shattuck et al. (2011) supports this hypothesis. Using a nationally representative sample, the authors found that nearly 40% of youth with ASD were receiving no services in the 2 years following their exit from high school. Furthermore, youth whose families had lower incomes were more likely to be without formal services relative to youth whose families had higher incomes. It appears then that youth with ASD whose families have fewer economic resources also receive fewer adult services once they exit high school and services are no longer mandated, which likely explains (at least in part) why the pattern of improvement in their behavior problems that was observed while they were in high school is more negatively impacted by exiting high school.

In sum, the small body of existing research focused on the transition to adulthood for youth with ASD suggests that it is a disruptive influence in the lives of these families, with the greatest disruption occurring for those who do not have ID, those whose families have fewer resources, as well as those who are underserved by the formal service system. In the following section we discuss the numerous directions for future research.

Future Directions

Although our knowledge of how youth with ASD and their families are impacted by the transition to adulthood is in its infancy, it is critical that we better understand the mutable factors associated with a positive transition. As previously mentioned, employment and vocational outcomes of adults with ASD have much room for improvement. Furthermore, adults with ASD seem to be at additional risk for poor outcomes relative to even adults with other types of developmental disabilities. Esbensen et al. (2010) found that adults with ASD had less optimal outcomes (as defined by less independence in their living arrangements, in

their vocational placements, and less social connectedness) relative to a matched group of adults with Down syndrome. It appears then that adults with ASD might be a particularly vulnerable group as they move out of high school and into adult life.

Future research should focus on the mutable factors that promote a successful transition to adulthood and optimal adult outcomes. So far, studies of risk factors for poor adult outcomes have focused on factors that are static and difficult to change. Adults with ASD who require substantial supports tend to have lower IQ scores, fewer functional abilities, and poor early language skills (Billstedt et al. 2007; Eaves and Ho 2008; Farley et al. 2009; Howlin et al. 2004; Howlin et al. 2000). But while knowing an individual's IQ and early language abilities helps predict adult outcomes, this information is less helpful in considering ways to improve outcomes. Malleable factors that impede positive outcomes or exacerbate negative outcomes may provide better avenues for intervention.

One promising factor is behavioral functioning, and specifically maladaptive behaviors. Maladaptive behaviors can be extremely disruptive for all adults with disabilities, including those with ASD. Taylor and Seltzer (2011b) found that young adults with ASD who had lower levels of maladaptive behaviors were more likely to be in college or working independently in the community in the years after high school exit. Those young adults with higher levels of maladaptive behaviors tended to either spend their time in sheltered settings (day activity programs, sheltered workshops) or to have no vocational activities. Maladaptive behaviors can be changed through both behavioral and pharmacological interventions (Aman et al. 2009; Matson et al. 2009; McCracken et al. 2002; Vismara and Rogers 2010), and thus constitute a promising factor that, if alleviated, could promote independence and employment among adults with ASD.

Environmental resources are another set of malleable factors that have virtually been ignored by researchers studying outcomes for adults with ASD. Not only are the quality and availability of formal services likely important in promoting a

positive transition to adulthood, but also the family environment. Family environments, characterized by high levels of criticism of the individual with ASD, predict significant increases in behavior problems (Greenberg et al. 2006); alternatively, supportive, warm family environments predict decreases in behavior problems for these adults (Smith et al. 2008). Environmental resources can be altered through advocacy for better disability-related services and psychoeducational intervention to improve positivity in the family environment (Bernhard et al. 2006), and thus are also promising avenues for future research focused on promoting a positive transition to adulthood for youth with ASD.

Finally, researchers should continue to consider what is meant by a "positive" transition to adulthood. Based on the current criteria for successful adult outcomes – living independently, working independently, and friendships – it is not difficult to come up with examples of young adults with ASD who appear to be transitioning "unsuccessfully," but in actuality may be doing quite well in adulthood. A more holistic view of the transition to adulthood would be garnered by including measures of life satisfaction, community engagement, sense of purpose, or even by judging outcomes based on individualistic goals for adult life. Measuring constructs broader than employment and living arrangements when examining an individual's transition success may also alleviate some of the bias against a successful transition for those young adults who have more functional limitations. Advocating the inclusion of measures of life satisfaction or purpose does not mean to imply that the difficulties faced by individuals with ASD in attaining community employment and independence are not concerning, only that it does not represent the entirety of the transition to adulthood.

Advocacy

Debra Dunn

The Center for Autism Research, The Children's Hospital of Philadelphia, Philadelphia, PA, USA

Definition

Advocacy refers to the process by which an individual or a group of individuals support(s) a cause or protect(s) the rights of an individual or group of individuals. Disability advocates can be parents, professionals, or individuals with disabilities themselves (known as self-advocates). Advocacy exists on multiple levels, ranging from the individual level to advocacy related to change of social policy.

Historical Background

Historically, advocates have been involved in many different issues, including education, healthcare, employment, housing, social opportunities, and more. In the education arena, advocates have been responsible for much of the legislation related to the special education laws in the United States. For example, a group of parents working with the Pennsylvania Association of Retarded Citizens (now known as the ARC) filed a complaint which eventually led to the passage of The Education for All Handicapped Children Act, the precursor to today's Individuals with Disabilities Education Improvement Act (IDEIA). Through advocating at the national and state level, these advocates have sought to ensure that all children with disabilities receive a free and appropriate public education. With regard to autism spectrum disorders (ASD), many advocates have pushed states to pass autism insurance legislation, in an attempt to prevent insurance companies from denying services to individuals with ASD. Currently, almost every state in the country has adopted or is considering autism insurance legislation. Advocates have also been involved in protecting the personal rights of individuals with

disabilities. For example, advocates in states such as Pennsylvania have proposed adult protective services laws, which would protect adults who are physically abused but unable to testify in court due to communication difficulties. This is particularly important in cases where physical evidence points to abuse, but a disability such as autism prevents the victim from testifying.

On an individual level, parents have always needed to advocate for services for their children with disabilities. In the education system, Congress has encouraged the development of parent advocates by increasingly including provisions in legislation which encourage parent involvement in educational decisions for their children. For example, parents are mandated participants in the process of developing individualized education programs (IEPs) for their children and are an integral part of IEP teams.

Similarly, Congress has empowered individuals with disabilities with rights to participate in their own education decisions. This has helped to create a new generation of self-advocates. At the age of 14, students with disabilities are invited to take part in the IEP process. Many IEPs for students with disabilities, including autism, include self-advocacy goals to help students learn to effectively communicate their needs and opinions. As a result, more and more individuals with disabilities are becoming adults who possess effective self-advocacy skills. Not only are these adults adept at advocating on their own behalf, many of them effectively advocate for broader social change. Today, individuals with disabilities sit on national, state, and local advisory boards, which are charged with developing policy that directly affects the disability community.

The role of the professional advocate has also developed over time, particularly as the education and other service systems have expanded and become more complex. Attorneys are advocates by virtue of their training, but increasingly other professionals have labeled themselves as disability or child "advocates." These professionals are not regulated nor accredited by any board. Nonetheless, many of them have a wealth of experience, which families have found helpful in advocating for services for their children.

Current Knowledge

There are a number of different disability advocacy organizations that exist today. Two of the oldest are the ARC (formerly Association of Retarded Citizens) and TASH (formerly American Association on Mental Deficiency). The National Disability Rights Network (formerly the National Association of Protection and Advocacy Systems) began more recently in the 1980s. As the prevalence of autism spectrum disorders has increased over time, advocacy organizations specific to ASD have been formed. Current autism advocacy organizations include the Autism Society of America, Autism Speaks, AutismNOW, Autism National Committee (AUTCOM), Autism Network International, the Autism Self Advocacy Network (ASAN), and the Global and Regional Asperger Syndrome Partnership (GRASP). The last four of these groups are self-advocacy organizations. Local autism support groups may also function as advocacy organizations; additionally, these groups can be effective at teaching parents to become more effective advocates.

Future Directions

Many advocacy organizations set short- and long-term agendas for their advocacy efforts. In the autism community, insurance legislation remains an area of concern in a handful of states across the country. Furthermore, despite new insurance laws in many states, funding for autism services remains incomplete and inadequate. Many advocates are expending great efforts to ensure that Medicaid and other federal and state programs are supported in the budget processes. Other legislations that are currently supported by autism advocates include the IDEA Fairness Restoration Act (to override a Supreme Court decision disallowing parents to be reimbursed for expert witness fees), the Combating Autism Reauthorization Act of 2011 (providing support for research into the causes and treatments for ASD), the Caring for Military Kids with Autism Act (to reverse a Department of Defense healthcare provision which does not recognize

autism as a treatable condition), and the Autism Service and Workforce Acceleration Act of 2011 (to develop comprehensive treatment centers and to improve the transition into adulthood for youth with ASD). When legislation is involved, some advocacy organizations will distribute action alerts to their constituencies to encourage interested parties to send letters to legislators and public officials.

In addition to legislation, court cases may arise which affect the rights of individuals with disabilities. Advocacy organizations may submit amicus briefs related to a particular issue that affects their constituency. The self-advocacy organizations, in particular, have submitted amicus briefs in employment cases and cases involving restraint and seclusion.

Going forward, as more and more children with ASD age into adulthood, advocacy efforts may begin to focus even more toward issues related to employment, housing, and adult services. New legislation regarding autism insurance will lead to more questions related to its interpretation, and advocates will be needed to represent the interests of individuals with ASD and their families. Indeed, funding will likely always remain a key area of advocacy efforts, given persistent budgetary constraints. In the education arena, in addition to the pending legislation related to expert witness fees in special education cases, federal legislation regarding the allocation of burden of proof in special education cases may be proposed. Currently states differ as to who has the responsibility to prove the case when the parent files the lawsuit but the educational authority (the school district) has the most access to evidence.

Another development related to advocacy may be the development of more training programs for professional advocates. There are advocate training programs hosted by a range of organizations, from law schools, to educational agencies, to private individuals and companies. Many of these training opportunities have been helpful in educating parents about their own rights and may offer a broader perspective that enable these parents to better assist other parents as well. Nonetheless, as advocates become more involved in

assisting parents in special education due process proceedings, there could be momentum to regulate advocate certificates (insofar as the certificates being offered do not provide licensure or credentialing).

Affective Development

Nurit Yirmiya and Ifat Seidman

Department of Psychology, The Hebrew University of Jerusalem, Jerusalem, Israel

Definition

Affective development pertains to the emergence of the emotional capacity to experience, recognize, and express a range of emotions and to adequately respond to emotional cues in others. Emotions such as happiness or fear are defined as subjective reactions to experience that are associated with physiological and behavioral changes. Emotional functioning comprises several aspects, including the inducement and elicitation of internal physiological states, the physiological pathways that mediate these internal states, the emotional expressions, and the perception of affect. Overt manifestations of affective expressions and responses include facial expressions, voice, postures, and movements. Affective development is intertwined with the development of social skills, and this psychosocial combination reflects one's distinctive personality and tendencies when responding to others, engaging in social interactions, and adapting to the interpersonal world (Saarni et al. 2006).

Individuals with autism have difficulties in emotional expressiveness and responsiveness and in the appropriateness of these emotional manifestations to the social context. Individuals with autism may exhibit limited empathic responsiveness and may demonstrate specific difficulties in face perception and face recognition, emotional regulation, and engagement in affective and social behaviors and contact with others. Some individuals with autism seem to manifest emotional flatness or aloofness and seem unresponsive to the social environment. It is most challenging for individuals with autism to reason about the emotional world of oneself and others, thus making it more difficult to successfully engage in social situations (Sigman and Capps 1997).

Historical Background

Kanner (1943) originally wrote that children with autism “have come into the world with innate inability to form the usual, biologically provided affective contact with people, just as other children come into the world with innate physical or intellectual handicaps.” (p. 250). Children with autism were originally described as aloof, unresponsive, or even emotionally detached, and the first studies regarding affective development in autism examined this issue of children’s emotional expressiveness. Early reports indicated that children with autism did not appear less emotionally expressive than children with mental retardation or than typically developing children (Capps et al. 1993; Ricks and Wing 1975). However, parents reported that their children with autism experienced higher levels of negative emotions such as fear, sadness, and anger and lower levels of positive emotions such as joy and interest, compared to the reports of parents of children with mental retardation and typically developing children (Capps et al. 1993). Researchers investigated whether children’s emotional expressions and responses (e.g., smiles, laughter, or even temper tantrums) were socially adequate and context appropriate. Findings revealed that children with autism sometimes manifested discordant affects or deficits in displaying positive affect and coordinating gaze with emotional expression to reveal sharing of emotional experience (Kasari et al. 1990, 1993; Yirmiya et al. 1989). For example, children with autism generally did not look up at their parents and smile when responding to parental praise for an accomplishment, whereas children with typical development or mental retardation generally did. Other studies on children with autism pinpointed difficulties in coordinating and pairing facial expressions with vocal expressions of emotions, with prosodic and linguistic expressions of emotions, or with body gestures (Hobson 1986; Van Lancker et al. 1989). Interestingly, most studies on children and adolescents with high-functioning autism or Asperger syndrome revealed no difficulties in labeling facial expressions, especially of the basic emotions of happiness, sadness, anger, fear, surprise,

and disgust (Braverman et al. 1989; Capps et al. 1992; Hobson et al. 1989; MacDonald et al. 1989; Ozonoff et al. 1990; Yirmiya and Sigman 1991). Current studies are now focusing on measuring emotional recognition abilities and more subtle emotions in individuals with autism with normal intelligence using more fine-grain measures (Golan et al. 2006, 2008; Happé 1994).

These atypicalities in affective development are currently widely accepted as features of autism, but their underlying causes remain a matter of debate. Some investigators consider the difficulties in affective development as secondary to, or as the result of, impairments in the development of social-cognitive abilities such as perspective-taking capacities or theory of mind (ToM) abilities (Baron-Cohen et al. 1985; Happé and Frith 2006), whereas other investigators consider abnormal affective development to be a core deficit in autism (Hobson 1993). According to the latter approach, individuals with autism reveal difficulties in their biologically based and innate capacity to perceive, decode, and understand emotional cues and expressions, which results in a failure to establish the mentalizing functions needed for appropriate social interactions. Today, there is growing awareness that mentalizing and ToM abilities contribute to the understanding of emotions and vice versa. Two-year-old toddlers are already able to decode facial expressions, but only a year later – using the emerging ToM abilities – can they also recognize the internal mental or emotional states that are reflected by these facial expressions. In turn, young children’s growing understanding of basic emotions facilitates and promotes their mentalizing abilities and their comprehension that desires differ from reality (Sigman and Capps 1997).

Current Knowledge

Affective Development in the Early Years

Caregivers facilitate the affective development of their children by supporting and scaffolding the emerging emotional capacities of their children. Infants come into the world equipped with a strong drive to emotionally engage with others.

Newborns are prepared to engage in mutual affective regulation, a process by which the infant and the caregiver communicate emotional states to each other and respond appropriately and sensitively (Jaffe et al. 2001; Kogan and Carter 1996; Stern 1985; Trevarthen 1993; Tronick 1989; Weinberg and Tronick 1996). In the first weeks of life, babies fluctuate between several states of arousal such as crying, sleeping, drowsiness, and alertness, with limited ability to control and regulate these shifts. As the neurological and physiological system becomes more mature and integrated, and the environment provides responsive parental care, infants become better able to regulate states of arousal. They spend more time awake, looking around and exploring social stimuli such as faces, as well as smiling, cooing, and laughing. Their emotional states can be easily seen during parent–child face-to-face interactions, in which infants take an active part in mutual regulation by sending and signaling behavioral and emotional cues such as smiles, gazes, or vocalizations. This synchronized match or “dance” between parent and child is an important mechanism underlying socio-affective development and is considered a prerequisite for later emotional functioning, empathy, and prosocial behaviors (Feldman 2007; Feldman et al. 1999). It was found that toddlers who showed high sensitivity and attention to emotional cues at the age of 2 years were more socially responsive with their peers, both at age 2 and at age 5. These factors may also render reciprocal effects, where children learn about emotions through their relationships with others. In sum, affective development in the first years is influenced by genetic, biological, and environmental factors and is strongly related to children’s temperament and to the development of the parent–child relationship and attachment.

Recent evidence is accumulating regarding different affective developmental trajectories of young children with autism, compared to children with typical development. Retrospective accounts, obtained from parents’ reports and home videotape analyses of the first 2 years, revealed that children with autism differ from children with typical development in social-

emotional behaviors, describing difficulties in affect regulation as well as increased negative affect and ambiguous affective expressions (Baranek 1999; Maestro et al. 2005; Osterling et al. 2002).

Prospective studies of siblings of children with autism – a group considered at risk for the development of autism and related difficulties – demonstrated that 12- to 18-month-old infants later diagnosed with autism are distinguishable from other infants who were not later diagnosed with autism in several social-emotional aspects, such as reductions in expression of positive emotion, social smiling, reactivity, and social interest as well as atypicalities in eye gaze, imitation, and orienting to name (Ozonoff et al. 2010; Young et al. 2009; Zwaigenbaum et al. 2005, 2009). Interestingly, these early manifestations were not extended downward; 6-month-old infants later diagnosed with autism were not distinguishable from 6-month-old infants who were not later diagnosed with autism in their affective expressions or in their social use of gaze and affect during social interactions with mutual sharing of attention and affect (Rozga et al. 2011). Furthermore, 24-month-old toddlers later diagnosed with autism were also distinguishable from their non-diagnosed peers in their temperament profiles, as marked by lower positive affect, difficulties in regulating negative affect, as well as lower feelings of excitement in situations of anticipation (Brian et al. 2008; Bryson et al. 2007). Thus, these important studies on the early affective development of young children with autism provide evidence regarding the presence of difficulties in affect displays and emotional regulation in the first years of life.

Affective Development in Childhood

Emotional development and sense of self are rooted in the experience of early childhood and continue to develop over the childhood years. Typical affective development in these years pertains to understanding and regulating emotions and to the organization of self-concept. As they grow, children become more aware of their own and other people’s emotions, can better regulate and control their feelings, respond with more

empathic behaviors, and show more acceptable emotional expressions. Through interacting with peers and their emerging friendships, children learn about their own emotions, become aware that individuals have different emotional reactions, and can better reflect on others' motives and intentions during complex social-emotional situations. Children must also cope with the emotional challenges associated with social developmental milestones during childhood, such as demands for social conformity, overt competition with others, and mastery of different academic skills (Saarni et al. 2006).

Children with autism face the same challenges as do typically developing children. Although some children with autism may master many academic skills, they have great difficulties managing everyday emotional and social situations in which an array of emotional and social cues must be recognized, interpreted, and synthesized quickly and simultaneously (Baron-Cohen 1995; Bauminger et al. 2008). Clearly, children with autism manifest great variation in their desire to form emotional connections with peers and adults, as well as in their ability to perceive and respond to the emotions of others. Studies regarding the understanding and experience of social emotions such as pride, embarrassment, or empathy revealed that school-age children with autism reported having these feelings as often as typically developing children; however, in their description of situations containing social emotions, they tended to describe more basic emotions (e.g., happy instead of proud) and to describe them more generally and less personally or interpersonally (Kasari et al. 2001).

Researchers examining affective development of children with autism also revealed strong associations between higher cognitive abilities and better understanding of emotional situations (Dyck et al. 2001; Golan et al. 2006), suggesting that cognition is an important moderating variable in affective development, as well as in compensatory strategies that children use to cope in emotional or social situations (Capps et al. 1992; Kasari et al. 2001). It has been suggested that the impaired performance of children with autism on measures of emotional functioning may be

secondary to difficulties in cognitive or ToM abilities, as well as to difficulties in linguistic and pragmatic capacities. Indeed, emotion perception difficulties are not specific to autism but have also been detected in individuals with other disabilities such as learning disabilities, mental retardation, and schizophrenia (Davis and Gibson 2000; Edwards et al. 2001; Zaja and Rojahn 2008).

Most of the evidence regarding affective development during childhood comes from studies of high-functioning children with autism. Children with autism who are low functioning in terms of cognitive abilities and are unable to speak and comprehend language continue to struggle with earlier affective developmental tasks even in childhood. They usually remain more engaged with objects and have few social interactions with peers, and they face challenges in learning alternative ways to communicate (Sigman and Capps 1997).

Affective Development in Adolescence and Adulthood

Adolescence, the developmental transition between childhood and adulthood, entails major physical, cognitive, and psychosocial changes. Adolescence enables vast opportunities for growth and autonomy and for its major developmental task – the search for personal identity. Adolescents must deal with physical alterations and sexual maturity as well as with the development of emotional independence from their parents and families by reorganizing their relationships with parents, siblings, and peers. Their emerging metacognitive thinking enables better comprehension and understanding of complex social and emotional situations, facilitating the capacity for self-consciousness and empathic responsiveness (Saarni et al. 2006).

Adolescents with autism have difficulties talking about their emotional experiences as well as about more complex social emotions other than the basic emotions such as happiness or fear. They also exhibit difficulties in their ability to empathize and recognize the emotions of others compared to adolescents with typical development who are matched on gender and on verbal and cognitive abilities (Capps et al. 1992). In their

descriptions of subjective experiences, adolescents with autism tend to attribute emotions to material circumstances and events rather than to interpersonal interactions or the attainment of a goal to a greater extent than do adolescents with mental retardation or adolescents with typical development (Jaedicke et al. 1994). For example, the descriptions of emotions by adolescents with autism tend to be more idiosyncratic and peculiar than the descriptions of emotions by adolescents in the comparison groups, who tend to link emotions to academic, social, and athletic successes or failures. Furthermore, the task of talking about feelings was more distressful for adolescents with autism; they appeared to struggle with the task and needed prompting and more time to respond compared to adolescents with typical development (Yirmiya and Sigman 1991). Interestingly, it has been demonstrated that adolescents with autism showed better emotional responsiveness abilities than younger children with autism when asked to respond to videotaped stories about children experiencing different events and emotions such as happiness, anger, or sadness (e.g., a boy is sad because he lost his dog). These findings suggest that as children with autism get older, their emotional responsiveness improves. However, these findings were not yet examined using longitudinal research designs and thus need further investigation (Sigman and Capps 1997).

As in childhood, during adolescence verbal and cognitive capacities play a major role in navigating one's developmental course. For some adolescents with autism, the widening gap with typical development may be associated with an aggravation of behavioral symptoms and poorer social functioning. It appears that the increasing complexity of adolescents' social and emotional world, and their engagement in more sophisticated interpersonal interactions, outstrips their advances in social and emotional functioning. Furthermore, difficulties in cognition and social understanding hinder adolescents' adjustment to their own growing physical and psychological alterations, making the adaptation process for this new developmental phase more challenging (Sigman and Capps 1997).

Few longitudinal studies have been conducted to follow children and adolescents with autism into adulthood; therefore, little information is available on affective development after this important turning point in life. The transition from adolescence to adulthood for individuals with autism is usually associated with exiting the school system and entering the adult service system, which is sometimes accompanied by the loss of many entitled services. There is evidence for social and psychiatric disorders in adults with autism that appear to increase with age. For example, adults with autism were found to engage in fewer social and recreational activities and also reported fewer friendships and peer relationships than at younger ages. However, other studies revealed that compared to typically developing individuals, adults with autism did not spend more time alone and were equally involved in social activities; however, they experienced increased social anxiety when in the company of less familiar people. Indeed, more longitudinal research is needed to expand this exploration of social functioning to incorporate emotional abilities in adulthood (Billstedt et al. 2011; Howlin et al. 2004).

Future Directions

Infants share common patterns of affective development; however, each infant shows a distinct emotional profile from the first days of life. Exploring the associations between early emotional style and later development of autism will contribute both to early identification of autism spectrum disorders and to early intervention programs (Dawson et al. 2010; Landa et al. 2010; Rozga et al. 2011). Furthermore, social interventions which are focused on understanding and recognizing more complex social emotions and mental states (e.g., embarrassment, irony) may strongly enhance problem solving abilities in social situations and social engagement (Lopata et al. 2010). Indeed, the issue of generalization of acquired social-emotional abilities to other social situations and to everyday life social interactions is most challenging, and further research is needed to evaluate the efficacy of social-emotional intervention.

Abstract

The people of Afghanistan continue to hurt from the effects of decades of invasion and civil war. While there have been some efforts to support the physically disabled population of Afghanistan, there is less support for individuals

with intellectual and mental disabilities; specifically, there is no support for children and adults with autism. This entry begins by introducing the history of autism-spectrum disorder (ASD) and the various legislative and political efforts in place in Afghanistan to support general disabilities. Furthermore, it addresses the lack of support for people specifically with autism in Afghanistan in regard to research and treatment of the condition. This is measured by the lack of nationwide recognition and awareness of autism, screening and diagnosis, and treatment for those afflicted with it. In addition to recognizing the severe lack of mental health resources in general, this entry also addresses the various cultural and social perceptual issues with autism and mental disabilities in Afghanistan. The aim of this entry is to acknowledge and understand the deep historical, political, economic, and social influences individuals and families affected by autism face in Afghanistan so that the country and its allies may begin to effectively tackle autism.

Historical Background

The earliest known description of autism was by Leo Kanner in the mid-twentieth century. In his report on 11 cases of children with seemingly autistic characteristics, he described these children as being removed from the social world and having a resistance to change or “insistence on sameness” (Kanner 1943). He believed that the condition they had was congenital. Autism was not recognized as an individual diagnosis right away as it was conflated with false leads and unclear symptoms (compared to other mental disorders such as schizophrenia) (Volkmar and Reichow 2013). At the time, parents (mainly mothers) were blamed for the condition of their children as there was a lack of understanding of the genetic cause of the condition. Autism was better understood in the 1970s after further quantitative research showed high rates of associated intellectual disabilities and a genetic basis for the condition (Volkmar and Reichow 2013).

Autism was first recognized as a mental disorder in the *Diagnostic and Statistical Manual of*

Mental Disorders-III (DSM-III) in 1980. The DSM-III was mainly focused on infantile autism and a child's lack of social responsiveness (Volkmar and Reichow 2013). The DSM-III included autism in a class of disorders known as pervasive developmental disorder (PDD) (Volkmar and Reichow 2013). Later revisions of the DSM-III such as the DSM-III-R, DSM-IV, and finally the current revision used today, DSM-V, included more accurate definitions of autism based on various reviews of literature and field studies around the world (Volkmar and Reichow 2013). In addition to having better diagnostic behavioral descriptions, it also adopted a refined description of the class of the disorder known as "autism spectrum disorder" (replacing PDD) (Volkmar and Reichow 2013). Today the DSM-V is used to screen and diagnose individuals who are at risk for autism. According to the Afghan Ministry of Public Health in the *National Mental Health Strategy 2009–2014*, diagnostic descriptions from classification systems such as the DSM-V or the ICD 10 (International Classification of Diseases 10) have limited utility in Afghan society (Ministry of Public Health 2009).

Research shows that structured behavioral, communicative, and educational intervention programs are effective and associated with better outcomes for children with ASD (Volkmar et al. 2014, volume 53, issue 2). The treatment options range from highly intensive and individualized one-on-one teaching every week to various pragmatic language skills training and group social skills workshops (Volkmar et al. 2014, volume 53, issue 2). Various institutions exist in America to support individuals with autism including specialized day schools and boarding schools. Other programs focus on training parents to be better caretakers for their children. Overall, there are a range of effective treatments and solutions for managing individuals with autism and teaching them effective social and life skills. Notably, the majority of these studies and treatments exist in affluent English-speaking countries such as the UK and the USA, and there is a severe lack of literature in effective treatment options for individuals with autism in developing countries (Samadi and McConkey 2011).

Legal Issues, Mandates for Service

When trying to understand the relevant policy and nationwide efforts concerning autism, it is important to note that, as is the case in other developing countries, autism is referred to as a general "disability" in Afghanistan. Therefore, policies and legislations that concern autism will fall into this general category rather than specifically focusing on autism. It is also important to recognize that a significant proportion of people categorized as "disabled" in Afghanistan are those who suffer from war-related injuries and illnesses rather than congenital disabilities such as autism.

In recent history, the Afghan government has taken various legislative steps toward advancing the rights of people with disabilities. First and foremost is the constitution of Afghanistan created in 2004 that addresses the rights and the inclusion into society of people with disabilities in the following articles (Sida 2014):

1. Article 22 prohibits any discrimination between Afghan citizens.
2. Article 53 provides for financial aid to persons with disabilities and guarantees their "active participation and reintegration into society."
3. Article 84 makes provision for two persons with disabilities to be appointed by the president as Members of Parliament in the House of Elders.

In addition to constitutional legislation, various national policies were also put into place to help people with disabilities. This included the *National Policy for Persons with Disabilities* created in 2004 which was joined with the *Afghanistan National Disability Action Plan (ANDAP)* in 2008–2011 to improve the access to education, employment, protection, justice, care, and social assistance and insurance for people with disabilities (Sida 2014). In recent years, the *National Law of Rights and Benefits of People with Disabilities* has further provided economic, social, and political support to people with disabilities and protected their rights and participation in society (Sida 2014). More specifically it allocated 3% of government and private sector

jobs to be reserved for people with disabilities. Another important governmental program is the *National Strategy for Disability and Rehabilitation 2013–2016* developed with the support of the UN and the EU (Sida 2014). However, it is important to note that these programs are largely concerned with physical disabilities, leaving intellectual disabilities on the periphery. Since many individuals with autism do not exhibit symptoms of a severe physical disability, this presents a challenge in addressing their needs.

Other outside parties have also tried to make strides in improving mental health services in Afghanistan for those who are disabled. According to the Human Rights Watch, the United Nations Security Council Resolution 2475 was recently adopted in order to protect and safeguard individuals with disabilities in areas of conflict. The resolution urged governments to enable the participation and representation of individuals with disability in humanitarian action and peacebuilding (Human Rights Watch 2019).

Overview of Current Treatments and Centers

Afghanistan severely lacks the institutions and training for a proper mental health system. Due to the decades of war and instability, much of the educated and professional workforce has left the country (Ventevogel 2006). There is a single mental health hospital in the capital city of Kabul and another single psychiatric hospital in Herat (Ventevogel 2006). Aside from other small inpatient facilities for psychiatric patients scattered around the country, there are no other viable options for individuals seeking mental health services. According to Peter Ventevogel of the UNHCR, the way forward in Afghanistan is to move away from hospital-based psychiatry toward a system of mental health integration in primary care services (Ventevogel et al. 2006).

Educational opportunities and resources for people with disabilities in Afghanistan are also quite limited. The Ministry of Education (MoE) is responsible for supporting inclusive education

and access to schools for children with disabilities as of 2004 (Trani et al. 2009). Other than nongovernmental organizations, the only governmental special education facility in all of Afghanistan is a nonresidential school for children with visual impairments in the capital city Kabul (90 children are enrolled). According to Jean Francois Trani, many of the problems both the MoE and the MLSAMD face in meeting the needs of people with disabilities are due to a lack of clear vision (Trani et al. 2009). There is inability to expand the definition of disability, and while there are many programs that cater to the needs of war-disabled people, there are less programs dedicated to those with congenital disabilities. Other obvious concerns are continual conflict and war, insufficient financial resources, and an inability to reach individuals in rural areas of the country. The lack of infrastructure and efficient transportation routes in Afghanistan makes any effort to send aid to disabled citizens living in rural areas difficult.

When the Republic of Afghanistan was established in 2003, the government inherited decades of turmoil to healthcare institutions and a population in great demand of medical attention. A major problem the country faces is a lack of funding for mental health services. In 2004, the health budget of Afghanistan was 289.4 million USD, but only 100,000 USD was allocated toward mental health (WHO-AIMS 2006, p. 1). A study conducted based on data from 2004 reported that there are only 34 hospital beds and 13 general practitioners per 100,000 population dedicated to mental health (WHO-AIMS 2006, p. 1). The private sector has an additional small percentage of hospital beds. Furthermore, the study showed that there are 3900 physician-based primary healthcare clinics in the country (about half private and half public) and 3100 non-physician-based primary healthcare clinics (WHO-AIMS 2006, p. 1). Recent legislative work in the area has focused on increasing psychosocial services in primary healthcare clinics.

The study by the WHO also showed that there are other mental health centers in the country including mental health outpatient facilities. There are 11 of these facilities in the country, and none of them are for adolescents or children.

The majority of patients seen at these centers are diagnosed with mood disorders or anxiety disorders. Day treatment centers are another type of resource; however, there is only one 1-day treatment center in the entire country. There are five community-based psychiatric inpatient units, but again none of these beds are reserved for children or adolescents, and the majority of patients have schizophrenia or mood disorders (WHO-AIMS 2006, p. 1).

It is important to notice that there is little to no attention to children with mental disorders or disabilities in Afghanistan. Not only are there no hospital beds specifically allocated for adolescents with mental health disorders, but there are also no institutionalized centers for screening or diagnosing mental health disorders. Parents who are worried about their child's behavior in cases such as autism have to take their children to psychiatric centers or mental health outpatient facilities designed for adults. There are no centers in Afghanistan for individuals who may potentially have autism to seek help or even receive a diagnosis.

The security crisis in Afghanistan presents another major challenge for any governmental or NGO initiatives related to autism. According to the WHO, in 2018 there were 85 attacks on healthcare centers in Afghanistan (World Health Organization 2019, p.11). Therefore, any community center or treatment center would have to take security concerns into consideration. For this reason, perhaps home-based or parental training services may be safer and have a larger impact on autism care in the short term.

Overview of Research Directions

A major problem for tackling autism in Afghanistan is surveying the prevalence of the condition in the country. The first step toward helping individuals with autism in Afghanistan is to find the distribution and prevalence of the condition in the country. This is necessary to make meaningful programming or policy-driven change for individuals with autism. In 2005, the National Disability Survey in Afghanistan

(NDSA) surveyed 5250 households for the prevalence of disabilities. The study found a general 4.6% prevalence rate (95% CI 4.4 to 4.8%) of disability in Afghanistan (Trani 2008). This amounts to approximately 1.09 million Afghans with some form of physical disability and/or mental distress (Trani 2008). Furthermore, the prevalence of individuals classified with "severe disabilities" was estimated at 2.7% of the population (Trani 2008). This was marked by individuals with functional limitations due to physical, intellectual, or sensory disabilities as well as mental illness. Jean-Francois Trani argues that surveys such as these must take a multidimensional approach using different instruments such as impairments, activity limitations, and assessments of well-being. Furthermore, studies of disability prevalence must go beyond measurements of prevalence and into the associations these disabilities have with individual's social agency and functioning levels in their environments.

Trani's criticism of the NDSA is important to acknowledge, especially when considering the possibility of a nationwide survey on the prevalence of autism. The National Institute of Mental Health characterizes autism as a "spectrum" disorder because there is a wide variety in the type and severity of symptoms associated with the condition (National Institute of Mental Health 2018). People with ASD have difficulty with social interaction and communication and may show restrictive and repetitive behaviors. However, when training professionals to screen for ASD, especially in developing countries, it is important to note that not all people with ASD will show these behaviors.

A study reviewing a 2011 initiative in Iran to identify autism prevalence in the country described two challenges in screening for autism in developing countries (Samadi and McConkey 2011). Since ASD is a condition with a wide spectrum of associated behaviors, the first challenge to the screening process is training professionals to oversee screening and diagnostic services. Also, since the majority of screening tests are made in developed countries with a different cultural context compared to Afghanistan, there is a need for a culturally relevant screening

process individualized to certain cultural contexts. The second challenge arises when using parental responses to interviews. Oftentimes, parents may not be educated or observant of the various signs that their children display (Samadi and McConkey 2011). As is the case in Iran, parents may even underreport their child's difficulties in order to keep them from being referred to special schools or in fear of social stigmatization (Samadi and McConkey 2011). This can cause survey results to indicate a lower prevalence of ASD than what actually exists. On the other hand, if parents also know that their child will be given specific aid or specialized attention, they may exaggerate their child's condition (Samadi and McConkey 2011). Since Afghanistan has many shared cultural contexts as Iran, many of these lessons are essential to keep in mind when designing a plan to screen the prevalence of ASD in the country.

Overview of Training

Training of mental healthcare professionals in Afghanistan is a present-day challenge, and many of the problems the country faced in the past still remain today. There is a lack of emphasis on the importance of mental health training in the country. A WHO study based on data from 2004 found that less than 1% of training for medical doctors in Afghanistan was dedicated toward mental health. Likewise, only 2% of training for nurses was dedicated to mental health (WHO-AIMS 2006, p. 1). The study further reported that only 2 psychiatrists, 61 other doctors, 37 nurses, and 40 other mental health workers worked in public mental health units (WHO-AIMS 2006, p. 1).

In addition to the serious lack of mental health training in Afghanistan, the WHO study also showed a severe shortage of mental health professionals in the country. The study showed a shocking number of only 0.5 human resource workers per 100,000 in the population (WHO-AIMS 2006, p. 1). There was a deficiency in the number of psychiatrists, medical doctors, nurses, medical assistants, and psychosocial counselors in Afghanistan. Furthermore, of the small number of psychiatrists and mental health

workers that did exist, almost none worked in community-based health centers or outpatient facilities (WHO-AIMS 2006, p. 1). In present-day Afghanistan, a shortage in funding toward mental health training and a shortage in mental healthcare professionals still exist. Furthermore, the majority of mental healthcare professionals work in adult mental hospitals, which, in the case of autism, would not be an appropriate place for one to take their child to be screened or diagnosed (World Health Organization 2019).

In 2009, the Government of the Islamic Republic of Afghanistan (GOIRA) and the Ministry of Public Health (MoPH) published a *National Mental Health Strategy* (NMHS) with the following aims (Sayed 2011):

- To promote mental health of the people of Afghanistan
- To minimize the stigma and discrimination attached to mental disorders
- To reduce the impact of mental disorders on individuals, families, and the community
- To prevent the development of mental health problems and mental disorders, wherever possible
- To provide quality, integrated, evidence and rights-based care for individuals suffering from mental disorders at all levels of health system

The program was completed in 2014 and aided the country in implementing a mental health plan to the country's Basic Package of Health Services. This includes a continuum of mental healthcare for Afghans with mental, neurological, and substance abuse disorders in hospital and community centers. Proving significant strides forward to the future of psychiatry and mental health training in Afghanistan was a study by Yousuf Rahimi in 2012 on the training of mental health professionals in Afghanistan. The study revealed around 60 locally trained psychiatrists working in the country (Rahimi and Azimi 2012). Furthermore, it was shown that neuropsychiatry was being taught in the latter years of medical school and that a 3–5-year postgraduate program was introduced in psychiatry by the

Ministry of Public Health, taking place in the psychiatric hospitals in Kabul and other regional hospitals (Rahimi and Azimi 2012). This shows a promising commitment toward mental health training in Afghanistan since the previous studies done in 2004.

Further showing that the future of mental health in Afghanistan is not all bleak is a recent publication on the importance of developing a culturally relevant counseling psychology degree program in Afghanistan. In the paper, researchers surveyed counselors studying at Kabul University and Herat University for their opinions on the qualities that are important for a counselor to possess. The Afghan counselors surveyed generally agreed that professionals must be knowledgeable on Afghan cultural values and customs, in addition to their expertise in international standards for counseling (Akeson et al. 2018). This is an especially important concept when it comes to leading initiatives related to autism in Afghanistan. This is because the majority of research and methods for coping with autism have been constructed in developed countries using Western individuals with autism. As the counselors recommended in the paper, it is important to consider the Afghan cultural and religious context when approaching any psychological condition.

Social Policy and Current Controversies

An important aspect of analyzing cultural perceptions of disabilities is through the lens of language. Language and words are the tools we use to understand the world around us. *Mayub* is the word in Dari (one of the two most common spoken languages in Afghanistan) that describes people who are disabled by birth through various congenital factors, diseases, or malnutrition (Bakhshi et al. 2006). *Malul* is the word that describes people who are disabled by an accident such as war, land mines, or sickness developed later in life. Finally, *diwana* is a colloquial word that relates to any impairment of the mind. This can mean intellectual disabilities as well as mental illness. People labeled as *diwana* face social stigmatization from both their communities and families (Bakhshi et al. 2006).

Unfortunately, oftentimes in Afghan society, individuals with mental disabilities are seen as *diwana* rather than *mayub*. A child who does not play with other children or does not make proper eye contact is seen as slow or intellectually challenged rather than disabled. Oftentimes families will look down upon this child and give more attention to the child who is funny, witty, or social. This causes further neglect to the child with a disability. Parents will see this as a phase or a learning problem that will fix itself over time. This can cause a major problem for children with autism by delaying the age at which the disability is detected. According to Autism Speaks, a diagnosis and intervention before the age of two maximize the progress of the child and ensure that they do not adopt harmful habits at an early age (Safa 2018). Another major challenge with mental disorders in general in Afghanistan is that oftentimes mothers are blamed for the condition of their child due to their bad parenting. This further delays the family from seeking professional help and opinions.

Cultural and religious stigmas cause problems for adults with mental disabilities and make it hard for these individuals to integrate into society (Trani and Bakhshi 2013). Studies show that in societies with social stigmas toward disabilities, individuals with such conditions are more prone to be poor and excluded from society (Braithwaite 2009). This can be in the form of social outcasting from their family or from society in general. It can cause intense feelings of shame and guilt for the individual with the disability (Trani and Bakhshi 2013). People with disabilities also face difficulty finding employment or finding partners for marriage. These problems are especially severe when the disability is due to congenital factors with no cure rather than war-related physical or mental disabilities (Trani and Bakhshi 2013). A 2004 study on the perception of disability within the Afghan community revealed a complex sentiment toward people with disabilities. War-related disabilities were viewed courageously as a noble sacrifice. This is not the sentiment with which congenital or nonwar-related disabilities are viewed (Bakhshi et al. 2006). Historically, Afghans have believed that individuals with epilepsy are possessed by *djinn* or evil spirits (Miles

2002). For individuals with autism, such religious and cultural stigmatization would further delay a proper diagnosis of the condition and thus delay treatment and rehabilitation.

Conclusion

It is evident that Afghanistan lacks the appropriate institutions and funding to uplift people with autism in the country. Although there has been significant work at a legislative level to be inclusive to people with disabilities, this work often excludes individuals with intellectual disabilities and especially people living in rural areas. A history of war has plagued Afghanistan with a national mental health crisis. This crisis includes not only mental disabilities but also post-traumatic stress disorders and various types of anxiety and depression. Furthermore, society outcasts individuals with intellectual and social disabilities such as autism as people who are *diwana*, or crazy, making it even more important for these issues to be adequately addressed. Unfortunately, international support on autism-related issues is lacking from both nongovernmental organizations and from researchers. There are no known studies looking at the prevalence of autism in Afghanistan, and organizations such as Autism Speaks do not operate in the country. The population of individuals with autism is an especially vulnerable group in Afghanistan, making it all the more necessary to build and fund institutions that support those with autism in Afghanistan.

AFLS

► Assessment of Functional Living Skills (AFLS)

Age Appropriate

Arlette Cassidy
The Gengras Center, University of Saint Joseph,
West Hartford, CT, USA

Definition

Age appropriate refers to a developmental concept whereby certain activities may be deemed appropriate or inappropriate to a child's "stage" or level of development. Specific disabilities as well as lack of exposure to age-appropriate activities and

experiences are commonly thought to prevent a child from gaining the skills necessary for their current and thus their next stage of development. It is thought that development most often occurs in rather predictable stages. Although every child develops in a unique way, all children are expected to interact with their environment at an age-appropriate level. Looking at a child's functional development involves observing whether or not the child has mastered certain developmental milestones and expectations for his or her age.

With this understanding of typical child development, a child may have a special need when he or she has a delay in one or more areas of development listed below:

Body movement
Thinking and learning
Communication
Senses and their integration
Relating to self and others
Self-care and daily living skills

Age Equivalents

Grace W. Gengoux
Child and Adolescent Psychiatry, Stanford
University School of Medicine, Lucile Packard
Children's Hospital, Stanford, CA, USA

Synonyms

Mental age; Test age

Definition

Age equivalent scores provide an estimate of the chronological age at which typically developing children demonstrate the skills exhibited by the child being assessed. The age equivalent score is based on the mean raw score on a test obtained by the group of children in the normative sample at a specific age. In simple terms, if on average children at 36 months of age obtain a score of 10 correct responses on a particular test, then any child obtaining a score of 10 correct will receive an age equivalent of 36 months. Age equivalent scores are often expressed in years and months (e.g., 5–0 for 5 years, 0 months).

Though age equivalent scores are appealing in that they appear to provide convenient descriptive information, they can be misleading and do not necessarily represent the level of functioning of the individual. For example, a 3-year-old child who receives an age equivalent of 4–6 on a test of expressive vocabulary is only similar to a 4½-year-old child in the number of items answered correctly on the test and does not necessarily share other characteristics of 4-year-old level expressive language ability. As an overall average of abilities, any age equivalent score should be interpreted with caution as the child may actually possess individual skills which fall above or below that level. Especially for children with significant scatter within their profile of abilities, these summary scores may provide an oversimplified picture of the child's skills. As development of skills is not linear, age equivalent scores do not represent equal units. Therefore a 6-month delay will have a different meaning for a 2-year-old child than for a 10-year-old child. Because they are based on ordinal scales, statistical computations such as standard error of measurement cannot be performed and confidence intervals cannot be determined. Correct interpretation of age equivalent scores must take these issues into account. In spite of these limitations, age equivalent scores may be especially useful when standard scores are not available, such as when a test is administered to a child with significant developmental delays whose chronological age falls outside the normative range for that test.

Age Period Cohort Analysis

Gayle C. Windham
Division of Environmental and Occupational
Disease Control, CA Department of Public
Health, Richmond, CA, USA

Definition

A “cohort” is a component of the population who shares a significant experience at a certain period of time or has one or more similar characteristics. A common usage for the term is to describe people born in the same time period as a birth cohort

(or generation). In epidemiological terms, it is used to denote a group of individuals sharing a common characteristic or experience, such as the same workplace or living near a waste site, who are observed over time for disease incidence and compared to a group without the characteristic, or to a general population (e.g., cohort study).

“Cohort analysis” is the calculation and analysis of morbidity (or mortality) rates for a particular disease in a birth cohort as they pass through various ages, with different cohorts overlapping at different ages in the same calendar time period.

Historical Background

Cohort analysis began as a tool to describe and understand mortality trends and is now commonly used to identify birth cohorts at higher risk for certain diseases, providing information for both public health surveillance and for the identification of etiologic factors. Age-period-cohort (APC) analysis refers to the interpretation of temporal trends in disease incidence or mortality rates in terms of three scales all related to time: age, calendar date (period), and year of birth (cohort). An *age* effect reflects the change in disease risk as a function of the age of individuals, such as cardiovascular disease, so differences in the age structure of samples being studied could affect disease incidence rates. A *period* effect refers to a change over time that tends to affect everyone regardless of age, such as an epidemic or a food contamination. A *cohort* effect is a variation in disease risk that applies to all individuals sharing a common experience associated with being born around the same time or in the same generation, such as change in exposure to a risk factor. Disentangling these effects can be quite difficult due to their interdependence; e.g., cohort effects are tied to both age and period effects (Fombonne 1994; Keyes et al. 2010).

Various graphical and analytic methods, including parametric and nonparametric approaches, for understanding trends in disease rates have been developed and received considerable attention in the literature (Glenn 1976; Holford 1983, 2005; Keyes et al. 2010; Kupper et al. 1985; Robertson and Boyle 1998). An early

method of statistical modeling of APC data was the multiple classification model, a model containing the effects of age groups (rows), periods of observation (columns), and birth cohorts (diagonals of the age-by-period table) (Kupper et al. 1985). The interpretation of such models is difficult due to the linear dependence between the three APC variables, which must be accounted for in the models. The various models basically treat the definition of the cohort effect in a different way; simplified, some models treat age and period effects as confounders of a cohort effect whereas others model the interaction, or effect modification, of age and period on the cohort. The decision of how to treat these variables is not really a statistical issue but rather depends on the study question of interest and how it is posed. Thus, the APC models are best used to organize and summarize data, potentially pointing out directions for future research to determine the true factors for which time is acting as a proxy.

Current Knowledge

Relevance to Autism

The reporting or prevalence of autism has greatly increased over the past few decades, but the reasons for the temporal increase continue to be debated (Croen et al. 2002; Fombonne 2003; Hertz-Picciotto and Delwiche 2009; King and Bearman 2009; Parner et al. 2008; Rice et al. 2010; Schecter and Grether 2008; Idring et al. 2015; Christensen et al. 2016). Several of these studies have examined age-cohort effects and observe increases for each age group in subsequent (more recent) cohorts. The reasons most commonly cited or examined for the increase include (1) younger age at diagnosis; (2) changes in diagnostic criteria, including shifts from other diagnoses (primarily mental retardation); (3) increased awareness of autism, so that ascertainment is improved or milder cases ascertained; and (4) true changes in the frequency, possibly via introduction of, or increase in, a variety of non-genetic risk factors.

Autism diagnosis is strongly related to age of the child, so shifts to younger ages at diagnosis

could artificially inflate prevalence rates among later cohorts if not taken into account in comparisons (Parner et al. 2008). Further complicating interpretation, age at diagnosis may be related to other factors such as child gender, race/ethnicity, IQ, and degree of impairment, as well as parental education, whose distribution could differ across cohorts (Christensen et al. 2016; Shattuck et al. 2009). Studies have not shown consistent effects of diagnostic shift or substitution on temporal trends, although its occurrence has been supported (King and Bearman 2009; Leonard et al. 2010). Differences in autism rates by race/ethnicity could reflect differential awareness and thus temporal trends as awareness increases and the racial distribution of cohorts change (Rice et al. 2010; Windham et al. 2011). Alternatively, racial differences may reflect access to services, for which temporal trends may be less predictable. As there is no biologic test or marker of autism, diagnosis is somewhat subjective. The medical and psychiatric criteria for diagnosis have changed over time since the 1980s, generally broadening, which might be reflected as period effects. However, the magnitude of effect of this change on prevalence rates is not agreed upon across investigators (Leonard et al. 2010). Further, the impact of the most recent diagnostic changes (DSM-5), which can be considered a tightening of criteria, has not been fully evaluated but may lead to leveling off of the increasing rates (Bennett and Goodall 2016; Maenner et al. 2014).

Two studies using data from California calculated age and birth year (cohort) rates in order to examine the impact of various factors, but without conducting formal APC analysis (Hertz-Picciotto and Delwiche 2009; Schecter and Grether 2008). Both showed that for each successive year of birth, incidence increased for each age, although more steeply for younger children in the 2009 analysis. Similar age-cohort patterns were seen in Stockholm (Idring et al. 2015). Hertz-Picciotto and Delwiche (2009) further attempted to calculate the proportion of increased incidence due to changes in age at diagnosis, diagnostic criteria, or inclusion of milder cases and found that while these explained some, they accounted for only about

a third of the overall change. One recent study based on similar California data but using an APC model (Keyes et al. 2012) reported strong cohort effects so that each successively younger cohort had higher odds of autism diagnosis, controlling for age and period effects. They concluded that the drivers of the increase in autism must be factors that have increased linearly year to year and aggregate in birth cohorts but did not examine specific causes.

Future Directions

Explaining the reasons for temporal trends of a health condition may provide important information for identifying, and thereby potentially ameliorating, risk factors for the disease, and for planning services. Studies show rising rates of autism by birth cohort that are not fully explained by diagnostic changes or awareness, so research to explain the increase is still very much needed. A variety of risk factors, from endogenous (such as parental age shifts) to exogenous (such as environmental exposures or maternal infection), are currently being investigated (Lyall et al. 2017). Formal APC analysis might shed some light by focusing investigators on factors that vary over time by birth cohort. The one study conducted thus far was based on only one of the possible models, however, so other models might not yield consistent results.

Acallosal syndrome; Callosotomy (surgical severing); Complete agenesis; Dysgenesis (malformation); Hypogenesis (partial formation); Hypoplasia (underdevelopment); Partial agenesis

Short Description or Definition

The corpus callosum (CC) is the largest white matter fiber tract (also known as commissure) connecting the two hemispheres of the human brain. Agenesis of the corpus callosum (AgCC) is present at birth and encompasses structural defects of the development of the corpus callosum that range from partial to complete loss of these connective fiber tracts. Primary AgCC is a complete loss of the CC without other accompanying brain changes. A rare individual diagnosed with ASD is found to have AgCC.

Categorization

The CC is generally divided into seven subregions.

AgCC is divided into *partial* (Fig. 1) and *complete* (Fig. 2) based on whether one or more subregions are missing (Fig. 1) or whether the entire CC is absent (Fig. 2). In both cases, the anterior commissure – a smaller white matter tract connecting ventral frontal regions – is almost always intact, with abnormalities limited to the CC.

Commissurotomy is a surgical procedure that typically involves severing all fiber tracts connecting the hemispheres, including the CC, to treat intractable epilepsy in which seizures that start in one hemisphere propagate to the

other hemisphere. Callosotomy is a subtype of commissurotomy that involves only severing of the CC.

Epidemiology

AgCC has been estimated to occur in at least 1 in 4,000 births, with one study identifying two cases in 2,309 neonates (Wang et al. 2004). AgCC is often associated with other developmental or neurogenetic syndromes including Arnold-Chiari malformation, Dandy-Walker syndrome, Aicardi's syndrome, holoprosencephaly, and numerous others. Approximately 30–45% of AgCC cases have currently identifiable genetic syndromes or chromosomal abnormalities. This percentage is likely to increase with advances in the sensitivity of genetic testing and the identification of new genetic disorders (Paul et al. 2007). For example, deletions on chromosome 1q42-q44 (Boland et al. 2007) and 14q12 (Shoicet et al. 2005), as well as multiple other chromosomal abnormalities (O'Driscoll et al. 2010), have been more recently identified.

Natural History, Prognostic Factors, and Outcomes

The CC is the largest and most important structure for interhemispheric transfer of information. It

Agenesis of Corpus Callosum, Fig. 1 Partial AgCC

Agenesis of Corpus Callosum, Fig. 2 Complete AgCC

contains fibers that connect both homotopic and heterotopic interhemispheric regions, meaning some fibers connect regions of the left and right hemispheres that are directly analogous (e.g., the left and right superior temporal regions), while others connect regions that are not directly analogous (e.g., the left superior temporal and right middle temporal regions). CC function was first examined by studying the cognitive skills of individuals who underwent commissurotomy or callosotomy, often called “split-brain” patients. These studies were useful for demonstrating specialization of the left and right halves of the brain. However, because these patients typically had surgical severing later in life, these studies did not provide information about the contributions of the CC to cognitive and brain development. More recent studies of babies and children with AgCC are providing data about the developmental role of the CC.

AgCC involves abnormal formation of the CC, typically between the third and 12th weeks of pregnancy, and is observable at birth via neuroimaging methods such as MRI. It appears that both genetic and environmental factors can play a role in the development of AgCC. Several genetic disorders and syndromes have been associated with AgCC, and evidence from animal work has shown the important roles specific genes play in the normal development of the CC. For example, individuals with X-linked lissencephaly (meaning “smooth brain”) have a mutation in the ARX gene and exhibit AgCC. In the developing brain, ARX proteins are involved with neuronal migration and deficient levels cause abnormal cell cycling and impair the migration of neurons (Friocourt et al. 2008) that should ultimately form the CC. AgCC also occurs in the context of in utero exposure to alcohol with <7% of individuals with fetal alcohol syndrome showing near complete AgCC and a greater proportion having partial AgCC or other CC malformations (Roebuck et al. 1998).

The cognitive impairments associated with AgCC are quite variable, although some consistent findings have emerged. Studies of younger children have identified developmental delay, learning difficulties, or behavior problems in the majority of AgCC cases (Goodyear et al. 2001;

Shevell 2002). Individuals with complete AgCC may have worse cognitive function and outcomes (Paul et al. 2007), although this has not been consistent across studies. Interestingly, although AgCC patients tend to show at least mild cognitive or behavioral difficulties, they do not exhibit the classic disconnection pattern shown by adult “split-brain” patients who had all commissures surgically severed, including the CC. Thus, individuals with congenital AgCC frequently show intact ability to transfer visual and auditory information across the left and right hemispheres. This may be because most AgCC patients have an intact anterior commissure and this structure may support some compensation of interhemispheric transfer.

AgCC can have substantial impact on specific cognitive functions. For example, many individuals with AgCC show significant differences in their verbal and nonverbal (visual) abilities, although which area is stronger varies across individuals (Chiarello 1980; Sauerwein et al. 1994). The most prominent deficits are in complex tasks that involve integration of multiple facets of information or rapid processing of complex arrays of stimuli. Thus, impairments may involve abstract reasoning (Brown and Paul 2000), problem solving (Fischer et al. 1992), and the ability to generalize a rule from one situation to another (Solursh et al. 1965) or to quickly generate examples from a category (e.g., specific names of animals or fruits and vegetables) (David et al. 1993). Deficits have also been observed in understanding pragmatic aspects of language, including problems in understanding idioms, metaphors, sarcasm, and other forms of nonliteral language and humor. Individuals with AgCC often show alexithymia or difficulty with verbally reporting emotional states and experiences. Parents of individuals with AgCC also frequently report social skill deficits.

Not surprisingly, given deficits in the processing of complex social and contextual information and parent reports of social weaknesses, AgCC has been identified in individuals diagnosed with ASD, or perhaps more accurately, some individuals with AgCC have been diagnosed with ASD. However, it is important to note that the vast majority of individuals with

ASD do not have AgCC and not all individuals with AgCC would be diagnosed with ASD. One study that sought to examine the prevalence of ASD-related symptoms in individuals with AgCC reported that 45% of children, 35% of adolescents, and 18% of adults with AgCC met criteria for ASD on the Autism Spectrum Quotient, a parent- and self-report screening tool for autism (Lau et al. 2013). Thus, the two conditions overlap, but are not redundant. The best-known example of this overlap is Kim Peek, the inspiration for the movie *Rain Man* who was widely known for his savant skills. These skills included photographic memory and an amazing ability to read and remember vast amounts of information in a short period of time. However, Kim Peek was not a typical example of primary AgCC because, in addition to having complete AgCC, he also was missing the anterior commissure, had macrocephaly and cerebellar malformation, and may have had a genetic syndrome (FG or Opitz-Kaveggia syndrome) linked to the X chromosome.

Adult outcomes of AgCC, even primary AgCC, are highly variable with some individuals showing intact overall ability and functioning and others showing significant intellectual disability and dependence on caregivers for even basic needs. Important prognostic factors related to this variability may include the level of agenesis (partial or complete) and the extent of other brain abnormalities.

Clinical Expression and Pathophysiology

As discussed above, clinical features are highly variable but include a wide range of deficits in general cognitive ability, large differences between verbal and nonverbal abilities, fairly consistent deficits in specific tasks that require rapid processing of complex information, social perception and skill weaknesses, and impairments in identifying/describing emotions (alexithymia). Developmental manifestations are not well known but are likely to be also highly variable with some individuals showing mild early delays with relatively intact functioning later in life and others showing consistently low levels of ability and functioning throughout the life span.

Evaluation and Differential Diagnosis

Asymptomatic AgCC is by definition hard to identify or diagnose since neuroimaging studies are not conducted without an indication. However, with prenatal ultrasound examination becoming more common and prenatal MRI being further developed, it is possible that identification of CC abnormalities may become more frequent. These alterations can be detected at 20 weeks of gestation, and once identified, associated features should be investigated (Vergani et al. 1994). In the majority of cases, a specific syndrome is diagnosed either during pregnancy or immediately after birth. In young children and older individuals, the presence of associated features such as seizures or developmental delays can prompt a comprehensive evaluation, including brain imaging that leads to diagnosis (see ► “American Academy of Neurology”). When AgCC is associated with a neurogenetic condition, the clinical features of this syndrome will be more evident. The list of conditions associated with anomalies of the CC is long and includes Chiari II malformations, Andermann’s syndrome (intellectual disability and polyneuropathy), and Joubert’s syndrome type III (absence of cerebellar vermis and polymicrogyria).

Treatment

There is no treatment for complete or partial AgCC. CC fibers will not regenerate and appropriately localize after that initial in utero critical period. However, given continued investigation into brain plasticity, even in adults, and a greater appreciation for the efficacy of early, intensive behavioral intervention and training, patients with AgCC may have therapeutic options in the future to help optimize their adaptive functioning. For instance, through greater understanding of the genes and biological pathways involved, it may be possible in the future for a combination of early detection and personalized genetic therapies addressing the specific molecular problems to optimize long-term outcomes in individuals with AgCC. Certainly, eliminating alcohol use in pregnancy, particularly in the first trimester, will reduce the number of cases of AgCC.

Description

The Ages and Stages Questionnaires (ASQ-3): A Parent-Completed Child Monitoring System, Third Edition (Squires et al. 2009) is a first-level comprehensive screening and monitoring program designed to identify infants and young children who require more extensive assessment to determine whether early intervention is warranted. It is designed to be easy to administer, low-cost, and appropriate for diverse populations, including children suspected of having an autism spectrum disorder. The monitoring system consists of two measures and associated user materials, the ASQ-3 and the ASQ:SE.

The ASQ-3 includes 21 questionnaires, one for each of the following ages: 2, 3, 6, 8, 9, 10, 12, 14, 16, 18, 20, 22, 24, 27, 30, 33, 36, 42, 48, 54, and 60 months. The questionnaires are designed to be completed by parents or other primary caregivers in less than 15 min and scored by a professional in less than 3 min. Each questionnaire contains 30 developmental items which are organized into five areas: Communication, Gross Motor, Fine Motor, Problem Solving, and Personal-Social. An Overall section addresses general parental concerns. In order to make the questionnaires user-friendly, items are written at a fourth to sixth grade level and illustrations are provided. For the 30 developmental items on each questionnaire, parents mark “yes” to indicate that their child performs the behavior, “sometimes” to indicate an occasional or emerging response, or “not yet” to indicate that their child does not yet perform the behavior. During the scoring process, each response is converted to a point value, values are totaled, and totals are then compared to established screening cutoff points. Each questionnaire comes with instructions, an information sheet for identification, activities for each social-emotional area, and an information summary sheet for scoring and general comments.

The ASQ:SE, which is used to screen for the presence of social-emotional delays, includes eight questionnaires, one for each of the following ages: 6, 12, 18, 24, 30, 36, 48, and 60 months. The measure addresses seven social-emotional areas: self-regulation, compliance, communication,

adaptive behaviors, autonomy, affect, and interaction with people. Like the ASQ-3, the ASQ:SE relies on parents to observe their child and complete the measure. Each questionnaire discusses social-emotional activities tied to the age of the child being screened, and by virtue of completing the questionnaire, parents learn about social-emotional milestones as well as their child’s strengths and vulnerabilities. For each item, parents mark “most of the time” to indicate that their child performs the behavior, “sometimes” to indicate an occasional or emerging response, or “rarely or never” to indicate that their child does not yet perform the behavior. Parents are also asked to check whether the behavior in question is a concern for them, and space is provided to allow for open-ended, narrative responding about certain aspects of their child’s social-emotional development. Much like the ASQ-3, each response is converted to a point value, values are totaled, and totals are then compared to established screening cutoff points. Following completion of the questionnaire, professionals may proceed with a referral for additional assessment and/or provide learning activity sheets to support the parent in further promoting social-emotional development.

Historical Background

In the 1970s, researchers at the University of Oregon, led by Dr. Diane Bricker, recognized the need for economical, valid, and culturally sensitive screening tools to identify young children who might be at risk for developmental delays. Following a landmark study on parents’ ability to report on their child’s early development (Knobloch et al. 1979), researchers including Dr. Bricker and Dr. Jane Squires conducted an extensive review of standardized developmental assessments and associated literature, and they selected a set of skills easily observed or elicited by parents within the home environment. Using these skills, Drs. Bricker and Squires created a series of questionnaires that asked parents simple questions about their child’s development. In response to pilot data, the questionnaires were expanded and refined, and in 1995, the

questionnaires were first published commercially by Brookes Publishing as the Ages & Stages Questionnaires® (ASQ): A Parent-Completed, Child-Monitoring System. In 1999, a revised and expanded edition of ASQ was published based on continuing research and user feedback. Data collection on the third edition, ASQ-3, began in 2002, and in 2009, the revised measure was published and an online management and questionnaire completion system was launched.

The ASQ:SE was created in response to growing demand for a screening tool for social-emotional concerns in young children. In 1995, the development process was initiated, and the first version of the Ages & Stages Questionnaires®: Social-Emotional (ASQ:SE) took form. Items in the early version of the ASQ:SE were developed using multiple sources, such as standardized social-emotional and developmental assessments, textbooks and other resources in developmental and abnormal psychology, language and communication materials, and education and intervention resources. In 1996, validity, reliability, and utility studies on a field-test version of the ASQ:SE were initiated. The field-test version was called the Behavior-Ages & Stages Questionnaires (B-ASQ; Squires et al. 1996). Following initial refinement, studies continued between 1996 and 2001 to determine the psychometric properties of the screening instrument, and in 2002, the Ages & Stages Questionnaires®: Social-Emotional (ASQ:SE): A Parent-Completed, Child-Monitoring System for Social-Emotional Behaviors was first published commercially by Brookes Publishing. Research on ASQ:SE is ongoing.

Psychometric Data

ASQ:SE: According to the publisher, normative data for the ASQ:SE were based on 3014 completed questionnaires, and validity studies were conducted using 1041 children. Internal consistency measured by coefficient alpha was found to be high across intervals, ranging from .67 to .91 with an overall alpha of .82. Test-retest reliability, measured as the agreement between two ASQ:SE questionnaires completed by parents at 1- to

3-week intervals was 94%. Sensitivity ranged from 71% at 24 months to 85% at 60 months, with 78% overall sensitivity. Specificity of the questionnaires ranged from 90% at 30 months to 98% at 6 months, with 94% overall. Percent agreement between questionnaires and standardized assessments/disability status ranged from 88% at 30 months to 94% at 60 months, with overall agreement of 92%. Under-referral ranged from 2.4% at 60 months to 4.7% at 12 months, while over-referral ranged from 3.0% at 18 months to 8.6% at 30 months. The ability of the ASQ:SE to detect atypical social-emotional development (sensitivity) was generally lower across intervals, while specificity, or the ability of the ASQ:SE to correctly identify typically developing children, was high. Specificity may have been elevated in the 6-, 12-, and 18-month intervals because of the large number of “identified” children in these samples and the small number of low-moderate risk children.

ASQ-3: The ASQ-3 has a new standardization based on a sample that closely mirrors the US population in geography and ethnicity and includes children of all socioeconomic statuses. The sample includes 15,138 children whose parents completed 18,232 questionnaires. According to the publisher, reliability, validity, sensitivity, and specificity are all excellent: Test-Retest Reliability = .92; Inter-rater Reliability = .93; Validity = .82 to .88; Sensitivity = .86; Specificity = .85.

Clinical Uses

Parents or caregivers complete the ASQ-3 and ASQ:SE questionnaires independently, or, if necessary, with the assistance of a professional. With online questionnaire completion through the web-based ASQ Family Access, parents are able to complete the ASQ-3 anytime, anywhere. The ASQ-3 and ASQ:SE questionnaires can also be completed on paper at home; during home visits by nurses, social workers, or program staff; in waiting areas; or in educational centers. According to the authors, the measures can be adapted to a variety of settings, including primary

care clinics, child care settings, and teen parenting programs. Both measures are designed for easy use and generally require little training, although it is important for professionals to be familiar with the information contained in the User's Guide. Many programs use the available DVD training tools to introduce the ASQ and show staff how to screen, score, and interpret results, and for programs desiring more training, the publishing company regularly hosts remote and on-site training seminars.

Agnosia

Claudia Califano

Yale-New Haven Hospital, New Haven, CT, USA

Definition

It is a partial or complete loss of the ability to recognize and identify familiar objects or persons through sensory stimuli. The specific sense is not defective nor is there any significant memory loss. People with agnosia may retain their cognitive abilities in other areas.

Agnosia may affect any of the senses and is classified accordingly as auditory, visual, olfactory, gustatory, or tactile agnosia. It can result from strokes, dementia, or other neurological disorders and illnesses. It may also be trauma-induced by a head injury, brain infection, or hereditary. Some forms of agnosia have been found to be genetic. It often results from damage to specific brain areas in the occipital or parietal lobes of the brain (Kolb and Whishaw 2003).

Agnosia is found in Landau-Kleffner syndrome, a disorder that is included on the differential diagnosis for autism (Johnson and Myers 2007). Landau-Kleffner syndrome (also known as LKS and acquired epileptic aphasia) is a rare childhood neurological disorder characterized by the loss of previously acquired language milestones, an inability to understand the spoken word and an abnormal electroencephalogram (EEG). These children develop normally until between the ages of 3 to 6 in contrast to autism, which is manifest prior to the age of 3 (Landau and Kleffner 1957; Teplin 1999).

Regardless of cause, there is no direct cure for the agnosia. Patients may improve if information is presented in other modalities than the damaged one. Different types of therapies can help to reverse the effects of agnosia. In some cases, occupational therapy or speech therapy can improve agnosia, depending on its etiology.

Agraphia

Diana B. Newman
Communication Disorders Department, Southern
Connecticut State University, New Haven, CT,
USA

Synonyms

[Acquired dysgraphia](#)

Definition

Agraphia is an impairment or loss in the ability to write in individuals (most often adults) who had typical spelling and/or handwriting prior to brain damage, either sudden or progressive. Agraphia occurs as a result of damage to the cognitive, linguistic, and/or sensorimotor areas of the brain that support spelling and writing (Beeson and Rapczak 2004). Lesions in specific regions in these areas affect the ability to retrieve words and/or their spellings and/or to form the letters to write the words.

Agraphia may be broadly categorized into two types: central or peripheral. Central agraphia affects an individual's ability to spell, while peripheral agraphia is characterized by handwriting difficulties (Beeson and Rapczak 2004). Additionally, visual perceptual changes that impair handwriting are not uncommon in those with brain injury.

Although the characteristics of agraphia are similar to those of developmental dysgraphia, the defining feature of agraphia is a history of typical writing skills before writing difficulties appeared; therefore, agraphia is not seen in children and adolescents with autism spectrum disorders (ASD).

Aicardi Syndrome

Fred R. Volkmar
Child Study Center, Irving B. Harris
Professor of Child Psychiatry, Pediatrics and
Psychology, Yale Child Study Center,
School of Medicine, Yale University, New Haven,
CT, USA

Definition

A rare genetic in which the corpus callosum (the major connection between the right and left hemispheres of the brain) is either totally or partially missing. It is associated with other abnormalities including seizures and a form of infantile spasms as well as characteristic eye abnormalities. It is thought likely that the source of the condition is on the X chromosome (it is observed only in girls or in boys with Klinefelter's syndrome); it is also possible that the condition is lethal to males with typical XY chromosome patterns – i.e., that the pregnancies miscarry.

First recognized by Jean Aicardi, a French neurologist, in 1976, the condition usually has its onset in the first months of life. The condition is rare. Although very likely to have a genetic cause, it is thought that all cases arise as a result of new mutations.

Treatment involves symptomatic management and treatment of associated problems, e.g., seizures, feeding problems, and sometimes hydrocephalus. Although outcome appears to vary, the condition is associated with significant cognitive delays.

Akathisia

Lawrence David Scahill
Nursing and Child Psychiatry, Yale Child Study Center, Yale University School of Nursing, New Haven, CT, USA
Marcus Autism Center, Children's Healthcare of Atlanta, Atlanta, GA, USA
Department of Pediatrics, Emory University, Atlanta, GA, USA

Definition

AKATHISIA: Akathisia is an adverse medication effect described as an unpleasant feeling of restlessness. It is most often associated with antipsychotic

medication, but may occur with antidepressant medications such as serotonin reuptake inhibitors. In the class of antipsychotic medications, akathisia is more likely to occur with the older antipsychotics such as haloperidol, but it may occur with the newer antipsychotics such as risperidone. Patients typically describe a feeling of internal restlessness and an inability to sit still. The observer might see the patient jiggling a leg while sitting or even kicking the leg out from the sitting position. In more extreme cases, the person may be unable to sit at all and will get up and pace around the room.

The cause of akathisia is not completely understood. It usually does not improve with anticholinergic medications that are often effective for other neurologically based adverse effects of antipsychotic medications. The first response is to lower the medication, beta blockers, or switching to another antipsychotic medication may be helpful.

BARNES AKATHISIA SCALE: Barnes Akathisia Rating Scale (BAS) was introduced in late 1980s. It consists of four items that are divided into objective item, subjective item, and an overall global scale. It is the most commonly used scale for measuring akathisia.

Autism: Definition

The word autism comes from the Greek word “auto” and can be translated to selfish-ism. The autism spectrum is also called autism spectrum disorders (ASD) or autism spectrum conditions (ASC), with the adjective autistic sometimes replacing the noun autism.

Categorization

Autism is a spectrum of psychological conditions characterized by widespread abnormalities of social interactions and communication as well as restricted interests and repetitive behavior (<http://www.statemaster.com/encyclopedia/Asperger-Syndrome>). Asperger’s syndrome can be seen as a mild form of autism, and in DSM-5, Asperger’s was moved to sort under autism.

Natural History

Autism was first described in 1911 by Swiss psychiatrist Eugen Bleuler (1857–1939) who mentioned, not too distinctly, two forms: schizophrenic autism and infantile autism. Both terms have been taken up by later psychiatrists and applied, confusingly, to a number of apparently different groups of disordered and socially isolated individuals (Tantam 1980). While John Langdon Down (1828–1896) is best known for having described

Down’s syndrome (trisomy 21) and savant syndrome in his 1887 lecture, he made an additional very astute observation about what he called “developmental retardation.” Today, that condition is known as autistic disorder (Treffert 2006).

Some people with autism spectrum disorders give grandiose and detailed descriptions of their special interests. That grandiose factor points to a parallel between narcissism (a.k.a. “psychopathy light”) and alexithymia. All these disorders belong to the (old psychiatry) borderline group, while others are shy, passive in contact with other people, or vice versa: intrusive and talkative.

Michael Rutter (1978) held that all reports of autism must begin with the book *Autistic Disturbances of Affective Contact* (1943) by Leo Kanner (1894–1981) where he described autism and held that the disorder probably was due to an inherited deficiency.

The characteristic symptoms of autism can be summarized as being rigid, a lack of social or emotional reciprocity, reduced communication skills, and limited interests – the last, however, can be very sophisticated (DSM-IV). Author Malika Mokeddem, herself an autist, was addressed by a friend: “You talk like a book.” If an autistic child has difficulties in imagining feelings of other people that may be because such a child has a biological worldview. A personality theory based on a biological approach differs from a psychological theory. Therefore, the claim that autistic children would be able to assess other people’s personality is unlikely to be true. (Pragmatic) autistic children, however, are adept at determining if a person really loves them. They don’t talk to a person who just talks in a friendly way, but does not help them – and as such, one might add that they would not be in the first line of being victims of psychopaths, unless their curiosity takes over. Hans Asperger (1906–1980) wrote (according to Frith 1991): “To our great surprise, we have seen how autistic individuals with good cognitive ability almost always achieve professional success, often in highly specialized academic professions and in very high positions, preferably within theoretical fields” and “A number of successful musicians were treated at our clinic when they were children. This seemingly

surprising fact what such difficult and abnormal children can achieve at acceptable and even high levels of social integration can be explained if one studies this phenomenon somewhat closer.”

“Autistic children may . . . possess a surprisingly well-developed understanding of art and have a solid understanding when distinguishing between genuine art and kitsch. They may even understand works of art that many adults perceive as difficult, such as Romanesque sculptures and paintings by Rembrandt. Autistic individuals may correctly perceive both the events unfolding on the board as to what lies behind, including portrayed individuals’ characters and the mood that pervades the painting. One should not forget that many adults never achieve an equally well-developed understanding of art. This skill is closely related to autistic people’s tendency to engage in a very special form of introspection and their ability to judge other people’s characters.”

Related Studies of the Brain

Research on twins by Folstein and Rutter published in *Nature* 1977 demonstrated the genetic influence on autism. They later wrote that “autism is one of the best validated child psychiatric disorders that exist.” Here are clear key concepts and empirically demonstrated genetic influences (Bailey et al. 1996).

Although brain imaging with MRI has revealed specific anomalies in white and folded gray brain tissue for several of those disorders or conditions, the precise relationship between structural changes and changes in neuronal function and relations remains unclear. Over the past decade, great hopes have been directed toward brain imaging techniques such as PET, SPECT, and functional MRI (fMRI). Torsten Wiesel, Nobel Prize winner in Physiology or Medicine 1981, expressed his surprise at how the research field around the brain and vision has been developed and expressed a wish for more specific cell studies instead of just using MRI for locating different brain functions. Hope of early diagnosis may ultimately be directed toward integration of fMRI, cell studies, and specific genetic tests.

Gender Issues

Hans Asperger said (according to Frith 1991) that he had never encountered a girl with fully

developed autism, and in his textbook of 1952, he reaffirms that all young girls he had met with a full-blown autism had acquired the disease after suspected encephalitis. In the past, such girls were called pseudopsychopaths or were diagnosed ADHD. But those young girls who exhibited the typical Asperger’s variant of autism are now well documented; the fact remains that the vast majority are boys (Frith 1991). A gender-linked form of inheritance is fully consistent with this pattern. The genetic causes of autism are not fully known. Social expectations of boys versus girls should also be observed. In a 2011 summary, Michael Rutter reported significant progress during the years 2007–2010 understanding autism. A little later in 2011, Andrew Whitehouse et al. published their article that autistic traits can be early detected and that they have a rather moderate stability from early childhood into adolescence.

Autism Disorder, Autism Spectrum, Autism Spectrum Disorders, or . . . ?

There is no univocal definition of the term autism spectrum. Connotated terms are attached like epilepsy, learning difficulties, delayed language development, self-injurious behavior, stomach problems, ADHD, tics, clumsiness, etc. Through a critical review of 69 research studies carried out between 1981 and 2010, Sharma et al. (2011) showed that six possible criteria (specifically the age at which signs and symptoms related to autism become apparent, language and social communication abilities, intellectual abilities, motor or movement skills, repetitive patterns of behavior, and the nature of social interaction) for diagnosing Asperger’s overlap with the criteria for diagnosing autism.

Hippler and Klicpera (2005) looked at Hans Asperger’s original data for the period 1950–1986 ($n = 181$) and performed a quantification of the two groups “autistic psychopathy” (AP) and autistic character (AZ). The latter group did produce less severe symptoms, higher intelligence, and communicative difficulties commonly associated with Asperger’s, while the AP group showed a broader symptom picture. Hans Asperger’s old term autistic psychopathy or elements of

psychopathy in autism is still used by some authors as well as in the *ICD-10*. It would be preferable to write autistic personality disorder or autistic personality spectrum. One of the cores of what we understand about psychopathy (nonexistent morals) has no place in an autism-Asperger's diagnosis.

Frith (1991), cited Hans Asperger: With concentrated energy and obvious confidence and, yes, with blinkers toward life's many possibilities, they follow their own path toward that which their talents have directed them since childhood – thus once again realizing the saying: “Man's good and bad qualities are only two sides of the same coin. It is simply impossible to separate them, to choose the good and reject the bad.”

Other researchers have asked autists and aspergians about their own perceptions of their situation. Respondents indicated an unusual perception and information processing, plus difficulty in regulating emotions – descriptions not included in the official DSM criteria. There are obviously different views on how aspergians and autists are to be understood.

The psychological dysfunction underlying the triad of impairments (imaginative thinking, socialization, and communication) could be described as the inability to put oneself in the position of another and to appreciate their thoughts, feelings, and wishes. This triad describes both Asperger's and autism. Obviously there is more to be said about imaginative thinking as, e.g., Einstein is considered to have had Asperger's.

There is no common understanding of the prevalence of Asperger's within the general population. Findings between studies differ but are usually below 1 %. 50 years after Hans Asperger's publication, it entered the *DSM-IV* in 1994. The removal of Asperger's from the *DSM-5* is likely to be controversial as the Asperger diagnosis is used by health insurers, researchers, state agencies, and schools – just to say nothing of people with the diagnosis, many of whom proudly call themselves aspies.

Several of this world's great thinkers are said to have been “suffering” from Asperger's like Socrates, Archimedes, Pythagoras, Julius Caesar, Napoleon Bonaparte, Charles Darwin, Albert

Einstein, Ludwig Wittgenstein, Bertrand Russell, Charles Babbage, Isaac Newton, Nikola Tesla, Kurt Gödel, Charles Lindbergh, John Watson, Alfred Kinsey, George Orwell, H. G. Wells, Ludwig van Beethoven, Wolfgang Amadeus Mozart, Georg Friedrich Händel, Pyotr Illyich Tchaikovsky, H. C. Andersen, Jane Austen, Immanuel Kant, and Alfred Nobel.

What would the world today look like if they had been prescribed selective serotonin reuptake inhibitors (SSRIs), fluoxetine, fluvoxamine, and sertraline for treating their restricted and repetitive interests and behavior?

Alexithymia

Alexithymia was introduced in 1973 by Peter Sifneos and was initially used for patients with psychosomatic disorders including a reduction in emotions, imagination, and finding words to describe their own feelings. Alexithymia is a cluster of cognitive and affective characteristics including difficulty identifying and communicating feelings, trouble distinguishing between feelings and somatic sensations of emotional arousal, impoverished and restrictive imaginative life, and a concrete and reality-oriented style (Taylor et al. 1997). Sometimes alexithymia has come to be associated with traditional masculinity in terms of negative characteristics as homophobia, violence, neglect of health, detached fathering and partnering, substance abuse, etc. (Levant and Richmond 2007).

If there is a common link between alexithymia and psychopathy, it may lie in the characteristic of *impulsivity*, so much in alexithymics that it seems to overcome their natural reluctance to break social conventions. Wastell and Booth (2003) have actually suggested that psychopathy should be viewed as alexithymia. Beginning with Niccolò Machiavelli's text (1513, 1987, *The Prince*), they argued that a psychopath is not a person who knowingly and intentionally manipulates his victims but instead is a victim of his own emotional limitations. A typical person with alexithymia is therefore anxious, overcontrolled, boring (Taylor et al. 1982), and submissive and

has a strict ethical approach. This puts alexithymia far away from psychopathy.

This last thing needs to be clarified; there is a significant positive correlation between secondary (anti-social) psychopathy and alexithymia, but not between primary psychopathy (often seen more stressing on genetic causes) and alexithymia. Alexithymia also seems to parallel Asperger's. Psychopaths on the other hand show low anxiety; are impulsive, dominant, charming, and deceitful; and do not necessarily try to fit in.

One case clearly showing how alexithymia and psychopathy can be mixed up is given by Ellis (2008). He described a man who killed his father without being aware that he was angry. He fully realized intellectually that the evidence (in the researchers' opinion) showed he *must have been* angry with his father, but he could not feel the anger. Perhaps he was not angry but just alexithymic? In short, there are similarities between alexithymia and psychopathy, but on ethical and moral issues, as in being able to lie and charm, psychopathy differs as much from alexithymia as it differs from Asperger's and autism.

There may be reasons for not considering the mild form of autism, Asperger's syndrome, as negatively and pathologizing as is being done today. Besides negative traits that are normally highlighted in the diagnosis, i.e., various aspects of so-called low social competence, one should take into account their high personal moral and personal care that often characterize individuals within the Asperger's syndrome (Dubin 2007).

There is a similarity between autism and narcissism in the young child and sometimes even in adults in their misapprehension of the reality or empathic understanding of other people's existence. "While a normal child is unaware of itself and adequately interacting with others as an integral member of the collective, the autistic child is constantly busy with observing itself. It is itself the object of interest and directs its attention towards its body movements" (Frith 1991). During the 1950s, Carl Rogers shed light on or specified empathy, saying that empathy is the ability to step into another person's shoes – and out again – thereby differentiating empathy from pity, compassion, and sympathy.

Empathy has two components (cognitive empathy and emotional empathy). The extreme emotional component can be illustrated by "rushing to the rescue" and the extreme cognitive aspect carefully planned rescue operation.

Autism, Alexithymia, and Humor

The presence of humor is a strong and useful instrument in psychodiagnostics with its requirements of verbal skills, social skills, and emotional and intellectual self-mirroring. But, as Hooker (1934) said, it can also be a matter of taste and as such difficult or impossible to define. According to psychoanalytic theory, a personality structure more developed than psychosis and borderline is required when dealing with jokes (you don't kid around with a borderline). People with early disorders (psychosis and borderline, i.e., borderline according to the old psychiatric nomenclature, before the DSM) perceive life in a black or white mode, good or bad, us and them (see Youtube.com or Google Videos: Pink Floyd, "Us and them"), and right or wrong – they see nothing in between.

Much of what most people see as humor is a verbal game with nuances and multiple meanings of words or expressions. Only neurotics and psychologically healthy people can make or understand jokes like that. Frith (1991), citing Hans Asperger, wrote that autistic children and those with Asperger's disorder have no sense of humor, especially if the joke is directed toward them. He held that it was partly due to that they are rarely relaxed and unconcerned. So individuals with Asperger's disorder are impaired in humor appreciation although anecdotal and parental reports provide evidence to the contrary.

The language of alexithymic persons has generally been described as flat and humorless, and subjects are characterized by cognitive, operative thinking. An often cited expression is the French "*pensée opératoire*" (operational thinking). It has been used in texts covering psychopathy, Asperger's, autism, and alexithymia but is most often used for the last group. "People who are managed by alexithymics sense their dullness and boredom quickly, and they become frustrated when attempts at interaction fail. Not even humor works" (Kets de Vries 2009).

Borderline individuals with their black or white, matter-of-fact behavior instead of empathic participation rather laugh *at* other people while neurotics and “non-disturbed” individuals laugh *with* other people.

Nature or Nurture?

Over the past 60 years, the pendulum of public and scientific opinion on the etiology of autism has swung between two extreme positions: (1) that autism is caused by some specific genetic abnormality, spawning a search for the “autism gene,” and (2) that autism is the result of some specific environmental factor or condition. There are three related potential explanations: the sociological, the physiological, and the developmental. When trying to explain autism, two positions have been suggested: a genetic abnormality and an environmental factor, including a “lack of maternal warmth.” Although the etiology of autism has remained elusive, the evidence to date has strongly refuted both of these extreme positions (Strathern 2009; Bumiller 2009). In parallel with the sociological explanation of psychopathy, maybe a sociological explanation for autism and Asperger’s can be seen in their wish for social acceptance rather than cures (Lawson 2008).

Some studies have found that parents of children with autism were more likely to have been hospitalized for a mental disorder. Those studies do however not agree on if the parents had their diagnoses *before or after* the birth of their child. Did parental disorder *cause* the child’s disorder or was it the other way around? To that comes the problem of differing between social heritage and genetic heritage. Usually, parents can detect interference patterns long before a formal diagnosis usually is given. Some parents to autistic children seem to feel lack of contact with their children before the children reach 18 months of age. That may explain some parents developing mental disorders *after* their child being born.

Different Levels of Achievement

Some of this world’s great thinkers are said to have been “suffering” from Asperger’s (above).

What a given individual eventually will achieve depends on a combination of genetic heritage and environment. To that come pre-, peri-, and post-natal damages; social heritage, cultural, and social norms and rules – or short: (genetic) heritage sets the roof, environment how close to the roof one will get – and how that roof is defined.

The Very Intelligent Individual’s Problem

More or less, all studies comment on the inability of others to understand the highly gifted. One way of handling that, e.g., was formulated by Leta Stetter Hollingworth (1866–1939): “Of all the special problems of general conduct which the most intelligent children face, I will mention five, which beset them in early years and may lead to habits subversive of fine leadership:

1. To find enough hard and interesting work at school
2. To suffer fools gladly
3. To keep from becoming negativistic toward authority
4. To keep from becoming hermits
5. To avoid the formation of habits of extreme chicanery”

The second point of Hollingsworth above could be of use for the highly gifted, as one way of handling that others don’t understand – although themselves not actually understanding that others don’t understand! A lesson many gifted persons never learn as long as they live is that human beings in general are inherently very different from themselves in thought, in action, in general intention, and in interests. Many a reformer has died at the hands of a mob which he was trying to improve. Leta Stetter Hollingworth also stressed the importance of providing a matching environment for highly gifted children.

Treatment, Education, or Just Acceptance

There is no unanimous definition of a successful treatment. Some say a successful treatment means the patient reports works or study and is happy living in a good relationship, others that the

patient just succeeded in going back to work, while still other definitions could be compared to the surgical concept of arthrodesis, and finally some say the patient just didn't kill himself.

Perhaps we should stop seeing autism as a medical disorder and instead see it as one of life's expressions. One can of course object that this is going a bit too far as there are different kinds of autistic disorders and that perhaps a third of them express some form of incomplete development, i.e., a health problem and not a matter of statistical discrepancy. With a diagnosis, parents may receive medical and psychological/educational support, while the child may be – and sometimes inaccurately – labeled and marked for life. Some autism researchers have expressed: The autism rights movement seeks acceptance, not cures. A parallel might be found in a highly intelligent and stimulus-seeking child misdiagnosed as ADHD.

Asperger/Autist: Truth Teller, Fundamentalist, Terrorist?

What will happen to the Asperger, the truth seeker, the truth teller? Adolescents and adults with Asperger's may engage in activities leading to fundamentalist religions (Attwood 2003). Maybe the Norwegian terrorist Anders Behring Breivik started as a rigid, principle-ridden Asperger's with an ideological goal (Norway only for Norwegians)? Different groups of experts in Norway have suggested diagnoses as narcissism, psychopathy, schizophrenia, or "no psychiatric diagnose at all." Niklas Långström said (2012) that Behring Breivik was neither psychotic nor suffering from substance use disorders, so there must be other explanations. Anders Behring Breivik may perhaps be seen as a truth-seeking aspergian, i.e., totally disregarding other people's views and feelings. With that, a new road for terrorist research on the consequences of fundamentalist personalities is indicated. When, and if, an aspergian develops toward "the pure thinking" of fundamentalism, the "medicine" is a dialogue, however, not an easy one. The method in question has a parallel in international styles of mediation (compared with the work of Jan Eliasson, Deputy Secretary-

General of the United Nations) between conflicting powers where presumably often "pure thinking" is involved among the parties or combatants.

In the Judiciary

Several researchers have pointed to major differences in moral and conventional behavior between most children and children with autism or ADHD and, on the other hand, child psychopaths and adult psychopaths scoring lower. In most countries, psychopaths are seen as fully responsible for their actions. Among those with Asperger's syndrome, there are at most 10 % with savant skills, and they are a problematic group for the judiciary. There is a need for a better understanding of Asperger's for those working within the criminal justice sector that lack the requisite training to respond effectively to those with Asperger's. As stated above, autists should be seen normal beings who want acceptance instead of cures. If that is so, they should be seen as normal responsible people even in a court. Asperger individuals and autists can, so to speak, meet with the judiciary in three instances: police, court, and in the question of sanctions. First, police needs more training. Second, in court psychopaths, Asperger people and autists should be treated as everybody else. Third, when it comes to issues of legal consequence or sanction, i.e., suspended sentence, probation, claim for damages, fines, restraining order, treatment (psychiatric), or prison, more research is needed.

Allen, Doris

Isabelle Rapin

Neurology and Pediatrics (Neurology), Albert Einstein College of Medicine, Bronx, NY, USA

Name and Degrees

Allen, Doris A., 1932–2002

BA – English/Speech Pathology/Audiology (1954)

MA – Applied Linguistics, Teachers College, Columbia University, New York City (1964)

MA – Psychology, Teachers College, Columbia University, New York City (1971)

EdD – Psycholinguistics, Teachers College, Columbia University, New York City (1973)

Major Appointments (Institution, Location, Dates)

Post doctoral Multidisciplinary Fellowship in Neuroscience, Albert Einstein College of Medicine, Bronx, NY (1974–1976)

Assistant Professor to Professor of Clinical Child Psychiatry and Clinical Pediatrics, Albert Einstein College of Medicine, 1977–2002.

Principal Investigator for the Autism Subproject – Diagnosis and classification of autistic children – of the NIH program project grant: Nosology: Higher Cerebral Function Disorders in Children (NS 20489) (1985–1993).

Major Honors and Awards

President's Scholarship, Teachers College, Columbia University (1964–1966).

Principal Investigator, NIH grant: The development of communicative competence in prematurely born children (1977).

Assistant Professor to Professor of Clinical Child Psychiatry and Clinical Pediatrics, Albert Einstein College of Medicine, 1977–2002.

Principal Investigator for the Autism Subproject – Diagnosis and classification of autistic children – of the NIH program project grant: Nosology: Higher Cerebral Function Disorders in Children (NS 20489) (1985–1993).

Landmark Clinical, Scientific, and Professional Contributions

(All at Albert Einstein College of Medicine, Bronx NY, USA)

- Director of the Therapeutic Nursery in the Division of Child Psychiatry of the Albert Einstein College of Medicine, 1978–1995. Director after its move to Tenafly NJ: 1995–2002.
- Developed a parent-child intervention model in the Nursery for educating preschool children with autism spectrum disorders without mental retardation.
- Trained generations of residents/fellows in child psychiatry, child neurology, and pediatrics to recognize milder autism spectrum disorders and how they can be managed effectively.
- Trained many graduate students and postdoctoral neuropsychology and speech/language pathology fellows in the diagnosis, education, and management of children with autism.
- Led the Einstein research group on language disorders in preschoolers.
- Was principal investigator of the autism subproject and investigator of the Autism Subproject of the multidisciplinary multiinstitutional Nosology project.
- With I. Rapin developed a neurologically and linguistically based clinical classification of developmental language disorders in preschoolers with/without autism for clinicians' use in their offices.

Short Biography

Born and brought up in Indiana, Dr. Doris A. Allen started her professional life as an English

teacher and mother of three sons. She subsequently relocated to New York, was remarried to Dr. Robert L. Allen, Professor of Linguistics at Columbia University where she obtained master's degrees in both psychology and applied developmental psycholinguistics and a doctorate in linguistics. After a 2-year postdoctoral fellowship in neuroscience at Albert Einstein College of Medicine, she was appointed to the faculty and as Director of the Therapeutic Nursery in the Division of Child Psychiatry. She turned it around from Freudian therapy of mothers to education of high functioning preschoolers with autism spectrum disorders (ASD), with a curriculum focused on social skills, communicative language, and self-management (Allen and Mendelson 2000). Dr. Allen recognized much earlier than most investigators that, besides severely impaired and intellectually deficient children with classic autistic disorder, there are many intelligent children on the autism spectrum for whom early, intensive, specialized intervention may enable them to grow up to become independent or nearly independent adults.

Dr. Allen developed the novel and highly effective parent-child model for the Nursery in which a caretaker attends school daily with the preschooler and is trained "in the trenches" to manage severe behavioral outbursts ("meltdowns") and to communicate more effectively with their child. Other family members receive some counseling as well, with tremendous improvement in the quality of life for everyone.

While at Einstein – and even now – the Nursery served as laboratory for research. Equally important, it provided the opportunity for physician trainees in child psychiatry, child neurology, and pediatrics to learn to spot mildly affected children likely to respond to appropriate educational intervention. Dr. Allen trained child psychiatrists, as well as graduate students and postdoctoral fellows, in psychology and speech/language pathology in the diagnosis, education, and treatment of children with autism. She was invited to lecture by many parent groups and at professional meetings in the USA and abroad.

Among her distinguished trainees are the child neuropsychologists Dr. Michelle A. Dunn, an

Einstein Professor, and Dr. Hilary Gomes, a Professor at City University of New York Graduate Center, who use electrophysiology to study language in autism (Dunn et al. 1999; Dunn et al. 1996). Dr. Dunn has developed an innovative visually based curriculum for children with ASD of all ages mainstreamed to regular classes (Dunn 2005; Fein and Dunn 2007). Another trainee, Dr. Mary Jure, has replicated with success the Einstein nursery in Cordoba, Argentina. Still another, Dr. Sylvie Goldman, studies narrative in children with autism (Goldman 2008), its male preponderance (Pfaff et al. 2011), and repetitive movements viewed as movement disorder rather than self-stimulation (Goldman et al. 2009).

Dr. Allen was the leader of the Einstein research group on language deficits in preschoolers (Allen 1988; Rapin and Allen 1987) and Co-principal Investigator for autism in the Nosology project (Fein et al. 1996). She stressed that effective remediation required subtyping of language deficits in order to address each child's needs individually (Allen et al. 1989; Allen 1994). She teamed with Dr. Isabelle Rapin, a child neurologist, to develop a neurologically and linguistically based clinical classification of developmental language disorders for nonspecialists applicable to any young child, whether on the autism spectrum or not. They found that there are several subtypes of language disorders in autism, including some affecting phonology and grammar (Allen and Rapin 1992; Rapin et al. 2009). Major distinctions between autism and developmental language disorders are different subtype prevalences, together with defective comprehension and universal and persistently impaired pragmatics (communication skills) in ASD. Dr. Allen coined the term semantic-pragmatic language disorder, now widely used, to describe chatty children whose expressive language is superior to their comprehension of discourse, whether or not they fulfill criteria for an ASD (Rapin and Allen 1998).

In short, Dr. Allen's interest in preschoolers with inadequate language and behavior and their treatment led to many publications, lectures, and the training of many professionals in the USA and

abroad. Perhaps her most enduring contribution is the innovative and effective model for educating preschoolers with ASD, as indicated by the majority of the graduates of her therapeutic nursery able to be educated in regular classrooms with or without the need for an aide and many among the older ones graduating from college or other higher education who are now independently employed.

Definition

An allergy is the body's exaggerated response to a foreign antigen (substance) or allergen that results

in an immune response leading to a reaction such as allergic conjunctivitis (itchy eyes), allergic rhinitis (runny nose), anaphylaxis (allergic shock), asthma, atopic dermatitis, eczema, hives, serum sickness, or contact dermatitis (skin rash). The body makes antibodies (immunoglobins) that attach to foreign particles like allergens and viruses to allow the immune system to dispose of them. People who are allergic to a compound will make the immunoglobulin type IgE in response to exposure to that compound. Common allergens include dust mites, animal dander, pollen, and foods. Allergic contact dermatitis is not mediated through IgE. While there is genetic predisposition to allergies, it requires a period of exposure (sensitization) for a person to make antibodies and develop symptoms. The production of antibodies in response to an allergen leads to allergic symptoms through release of chemicals such as histamine from the body's own cells which leads to inflammation. Allergies may start at any age. Some allergic manifestations such as asthma may be more problematic in childhood. Food allergies may present as tingling or swelling of the throat and tongue, nausea, diarrhea, skin reactions, or even anaphylaxis. The most common food allergens are milk, fish, shellfish, peanuts, tree nuts, eggs, wheat, and soy. Allergy workup may be initiated after a history of symptoms after exposure to an allergen. Blood tests such as the enzyme linked immunosorbent assay (ELISA) or radioallergen sorbent testing (RAST) may detect specific IgE antibodies associated with allergic response. Blood testing is not as accurate as skin testing. Skin prick, intradermal, or patch testing characterizes an individual's response to allergens administered using standard procedures and measurement of response.

The best treatment for allergies is to avoid the allergen responsible for symptoms. Symptomatic relief may be possible with antihistamines, eye drops, and topical or oral steroid preparations depending on the type of symptom. Treatment of asthma may require both management of the allergy and medication to address lung function. People who respond to allergens with anaphylaxis must carry epinephrine for injection since

anaphylaxis may be fatal. Allergy shots or immunoprophylaxis is a type of treatment that is usually supervised by a medical doctor specializing in allergy and immunology where small amounts of the target allergen are injected into a patient to help build up antibody response.

Aloof Group

Judith Gould

NAS Lorna Wing Centre for Autism, Bromley, UK

Definition

Lorna Wing and Judith Gould (1979) in their epidemiological study identified individual children who did not fit neatly into definitive categories but whose pattern of skills and behavior could be described as part of a spectrum of autistic conditions.

There were three aspects, social interaction, communication (verbal and nonverbal), and imagination. Children with difficulties in these areas also showed repetitive patterns of behavior. The manifestations of different problems in social interaction could be grouped into three types, Aloof, Passive, and Active but Odd.

The aloof group closely resembled the then popular image of autism which had been described by Kanner (1943) and Kanner and Eisenberg (1956). These individuals are the most cut off from social contact. If they do make contact, it is essentially needs led. They may respond to (and may initiate) physical contact only, including rough and tumble games, chasing, cuddling but are otherwise indifferent. This pattern of social interaction is linked with problems in understanding and use of verbal and nonverbal communication. Many persons in this group lack communication skills all their lives. If they do develop speech there are often unusual aspects of communication, e.g., echolalia, reversal of pronouns, repetitiveness, idiosyncratic use of words or phrases, and abbreviations of phrases. If they reach this level of communication, they will use the minimum number of words to convey basic needs. Most importantly, these children do not use speech as a means of social interaction. Speech is simply a way of getting what they want.

As children, most of the aloof group have no symbolic pretend play. They may manipulate objects but show no signs of pretending that toys represent real things. They do not build up an inner world of imagination for themselves. Instead, they fill their time with repetitive, stereotyped activities. Such children may engage for hours on one pursuit which totally absorbs them such as lining up toys or twiddling an object close to their eyes.

The more able aloof individuals may have complex elaborate repetitive routines such as collecting objects, organizing objects into patterns, bedtime rituals, and taking the same route to places. Aloofness and indifference to others are most likely to persist throughout childhood into adult life in individuals who are severely

intellectually disabled. The more intellectually able aloof group may demonstrate special skills usually in visuospatial skills and rote memory.

Definition

A prescription drug in the group of triazolobenzodiazepines in the family of benzodiazepines initially FDA-approved for medical use in the year 1981 with the chemical formula C₁₇H₁₃ClN₄. This compound has low water solubility and high lipid solubility. This drug acts as a central nervous system depressant and is mostly metabolized by cytochrome P450 (CYP450) enzyme 3A4. This high-potency benzodiazepine with a half-life of 10–15 h is FDA-approved for the treatment of panic disorder and anxiety disorders and can also be used to treat seizures, premenstrual dysphoric disorder, tricyclic antidepressant-related jitteriness syndrome, and valproate-induced tremors. Observed side effects include drowsiness, light-headedness, dizziness, depression, tiredness, nausea, insomnia, and diarrhea.

Alternative Communication

Vannesa T. Mueller

Speech-Language Pathology Program, University of Texas at El Paso College of Health Science, El Paso, TX, USA

Definition

Alternative communication (also called augmentative and alternative communication or AAC) is an area of clinical practice within the field of speech-language pathology. A definition of AAC is provided by the American Speech-Language-Hearing Association (ASHA). According to ASHA, AAC “includes all forms of communication (other than oral speech) that are used to express thoughts, needs, wants, and ideas” (ASHA 1997). The types of AAC include aided and unaided communication systems. Aided systems are those that require something other than the individuals’ body to communicate. That “something” could be picture symbols, written words, or a high-tech, speech generating device. Conversely, unaided systems are those that do not require anything separate from one’s own body to communicate. Essentially, gestures, body language, and sign language are examples of unaided systems.

Historical Background

The field of AAC began with the development of the International Society for Augmentative and Alternative Communication (ISAAC) in 1983. Before this, AAC was not a unified field and existed as a combination of interventions (communication boards and sign language) and products designed for individuals with speech and motor impairments. In fact, the use of augmentative or alternative communication for individuals with speech impairments may have first been introduced in the 1920s in the form of communication boards for individuals with cerebral palsy. The 1960s and 1970s saw an increase in the use of technology for AAC purposes. Typewriters that used innovative input methods such as a sip-and-

puff switch were invented. Speech-output devices were invented in the 1970s, and portable speech-output devices were available shortly thereafter. For a more detailed look at the early history of AAC, see Vanderheiden (2002).

The field of AAC has seen many changes in terms of application and philosophies. Early assessment models focused on AAC candidacy. Often much time and thought was spent examining a client's qualifications for AAC interventions. This resulted in the thought that many individuals were too "something" for AAC and therefore not deemed appropriate for AAC services. Individuals may have been seen as having too little linguistic functioning, too much linguistic functioning, too cognitively impaired, too high functioning, too limited motor abilities, etc. This resulted in many individuals who could have benefited from AAC technologies not receiving proper services.

Another factor which resulted in missed opportunities to provide AAC solutions was the erroneous idea that the use of augmentative communication would act as a crutch for individuals with speech impairments. It was feared by many in the field that those who used AAC would not learn to communicate vocally despite research to the contrary.

Rationale or Underlying Theory

The rationale for augmentative and alternative communication can be found in the term itself. AAC is first augmentative. The purpose for this type of intervention is to augment or supplement the speech an individual naturally possesses. For some individuals, however, this intervention is an alternative form of communication. These individuals have no means of verbal speech and so need to implement an alternative form. AAC is the means by which these individuals communicate.

Goals and Objectives

The goal of AAC is functional communication. Rate of message transfer is different for the different forms of AAC. Sign language, when produced

by a fluent signer, can be produced as quickly as spoken speech (Bellugi and Fischer 1972). However, communication through means of an alternative communication device occurs at an excruciatingly slow 15 words per minute (Foulds 1987) compared to 150–250 words per minute for speakers (Goldman-Eisler 1986). Therefore, rate of communication should not be expected to occur as fast as spoken communication for individuals who use aided systems.

Treatment Participants

Any individual who has impaired communication is a candidate for AAC. Therefore, because communication impairments are a hallmark of autism spectrum disorders (ASDs) (Mirenda 2009), most individuals with ASDs are candidates for a total communication approach.

The currently used assessment model is called the participation model (see Beukelman and Mirenda 2005 for a thorough description of the model). The model emphasizes those areas that an individual is not able to take part in due to their communication impairments. As such, this model is inclusive and appropriate for any individual who has communication needs in any area of their life.

Treatment Procedures

Using the participation model (Beukelman and Mirenda 2005) as a guide, AAC interventions focus on allowing an individual with speech impairment to participate in their environment to the same extent as that of their peers. Beukelman and Mirenda (2005) also give strategies and recommendations for implementing AAC for both nonsymbolic and symbolic beginning communicators. Nonsymbolic beginning communicators are those who use nonsymbolic communication such as gestures, facial expression, cries, or grunts. Symbolic beginning communicators use some form of symbolic communication such as words (spoken or written) or symbols with low- or high-tech communication devices. The authors state that "opportunity for communication is at

least as important to the success of a communication intervention as the availability of an appropriate system” (p. 272). Additionally, the authors provide techniques related to shaping intentional communication, using scripted routines, providing natural consequences, and using structured instructional techniques such as the adapted strategic instruction model (A-SIM), structured practice, and conversational coaching.

Efficacy Information

Efficacy research in the field of AAC is a relatively new addition to the literature. Bedrosian (1999) states that much early research in the field, as it should have been, was devoted to descriptive studies relating to describing the communication of AAC users. Since that publication, many more research studies have been conducted that are devoted to the efficacy of AAC for specific populations. Autism is one of those populations that has been widely studied. Overwhelmingly, the use of AAC has resulted in increased language skills in children with autism over treatment approaches that focus on speech alone. For most individuals with autism, accessing their relative strength in the visual domain has resulted in faster and more complex language growth in both signing and speaking. The use of manual signing in combination with speech training has been shown to increase language skill. The use of nonelectronic-aided systems such as picture use has also been shown to increase functional communication, and a wide range of individuals with autism have been able to make use of this type of communication. High-tech AAC use has been shown to increase language abilities and speech output in individuals with autism as well. See Goldstein (2002) and Mirenda (2002) for reviews.

A meta-analysis of available research related to AAC use was conducted by Millar et al. (2006). Although the meta-analysis was not focused only on individuals with autism, the major finding was that use of AAC does “not have a negative impact on speech production” (p. 257), and, in fact, speech production increased in individuals ages

2–60 years as a result of AAC interventions and across a range of different AAC interventions (aided and unaided).

Outcome Measurement

Because the goal of AAC use is functional communication, the outcome measurement should be the same. Functional communication of course will be defined differently based on the cognitive skills of the individual and the type of AAC system that is in place.

Qualifications of Treatment Providers

AAC interventions are most typically introduced by a speech-language pathologist. Unfortunately, many speech-language pathologists do not report having adequate training or education in the field of AAC (King 1998; Marvin et al. 2003; Simpson et al. 1999), and a survey of education programs for speech-language pathologists has uncovered a need for better education in this area (Ratcliff et al. 2008). Although this is the case, speech-language pathologists are the best equipped of all professionals who work with individuals with autism to provide intervention that includes AAC. A listing of speech-language pathologists who are certified by the American Speech-Language-Hearing Association can be found on their website. A few short questions posed to the speech-language pathologist can reveal whether they are comfortable with the area of AAC.

Alternative Diagnostic Concepts

Christopher Gillberg

Department of Child and Adolescent Psychiatry,
Gillberg Neuropsychiatry Centre, University of
Gothenburg, Gothenburg, Sweden

Definition

Clinical medical work without diagnosis is pointless. There can be no medical epidemiological study of psychiatric or developmental disorder without a consideration of diagnostic boundaries.

Diagnostic systems in psychiatric and developmental medicine are overarching models of symptoms, problems, functional restrictions, impairments, traits, signs, and psychological and biological test markers that constitute a particular disease, disorder, or group of disorders. Among these, the most influential are clinically based, generally agreed models such as the World Health Organization International Classification of Diseases and Disorders (ICD) (WHO 1993) and, for psychiatric disorders, the American Psychiatric Association Diagnostic and Statistical Manual of Mental Disorders (DSM) (APA 1994, 2011). However, there are also factor analytic models, signal detection models, continuous distribution models with statistically predetermined cutoff arbiters, and artificial network models, but these, in spite of being important for the development of new operationalized criteria for categorical diagnoses, have, so far, had relatively little impact in clinical practice. There are also taxonomies proposed by individual research groups who have developed alternative diagnostic systems that may – or may not – take into account the existence of the other clinically based models. This entry cannot avoid discussing modeling issues and the most commonly used clinically based systems, before going on to take a look at alternative diagnostic systems, including issues relating to multiple complex developmental disorder (MCDD), deficits in attention, motor control, and perception (DAMP), empathy disorders, nonverbal learning

disability, and early symptomatic syndromes eliciting neurodevelopmental clinical examinations (ESSENCE).

Historical Background

The ICD

The ICD is the international standard diagnostic classification for clinical practice and epidemiological and health management purposes. The current version (ICD-10) has a section for psychiatric disorder (including for autism or ► [“Pervasive Developmental Disorders”](#)) that is similar, but not identical, to that of the DSM-IV, which was published at about the same time as the ICD-10. Attempts were made during the development of the psychiatric section of the ICD-10 and the DSM-IV to streamline the two manuals. This was partly successful, but there are still considerable differences across the texts, criteria, and algorithms for diagnosing particular disorders, and some disorders appear only in one of the manuals.

Given that the DSM, compared to the ICD, has a much longer history when it comes to developing and analyzing operationalized criteria for psychiatric disorder, there will be a more detailed focus on the DSM than on the ICD. Much of what will be said about the DSM-IV (and the development of the DSM-5) applies in principle to the ICD-10 (and the development of the ICD-11, which is scheduled for publication in 2013).

The DSM

The Diagnostic and Statistical Manual of Mental Disorders (DSM-I) was published in 1952. The DSM-II, published in 1968, was 134-page long and listed 182 disorders. Both the DSM-I and the DSM-II reflected the predominantly psychodynamic psychiatry, although they also included biological perspectives and concepts from Kraepelin’s system of classification. Symptoms were not operationalized.

The criteria adopted for many of the mental disorders in the DSM-III (1980) were taken from the Research Diagnostic Criteria (RDC) and the Feighner Criteria, which had already been developed by a group of research-oriented psychiatrists.

Other criteria, and potential new categories of disorder, were established by consensus during meetings of the DSM committee. A key aim was to base categorization on descriptive language rather than assumptions of etiology. A new “multiaxial” system attempted to yield a “bigger picture.” When published, the DSM-III was almost 500-page long and listed 265 diagnostic categories. It rapidly came into widespread international use by multiple stakeholders and has been termed a revolution or transformation in psychiatry.

In 1987, the DSM-III-R was published as a revision of DSM-III. Six categories were deleted while others were added. The DSM-III-R contained 292 diagnoses and was 70 pages longer than the DSM-III.

In 1994, the DSM-IV was published, listing almost 300 disorders in just under 900 pages. The steering committee had created 13 work groups, who conducted a three-step process. First, each group conducted literature reviews of their diagnoses. Then they requested data from researchers, conducting analyses to determine which criteria required change, with instructions to be conservative. Finally, they conducted field trials relating diagnoses to clinical practice. A change from previous versions was the inclusion of a clinical significance criterion to about half of the categories. A “text revision” of the DSM-IV, known as the DSM-IV-TR, was published in 2000. The diagnostic categories and the vast majority of the specific criteria for diagnosis were unchanged (www.wikipedia.com).

Factor Analytic and Latent Class Models

Perhaps the most illustrative example of how factor analysis has been applied in clinical child and adolescent psychiatric/developmental diagnosis comes from the much-researched – and used – material developed by Thomas Achenbach (originally with colleague Edelbrock), often referred to as the “Child Behavior Checklist” (CBCL) or the ASEBA (Achenbach System of Empirically Based Assessment; Achenbach et al. 2008).

The CBCL/1.5–5 and the CBCL/6–18 includes 99/118 problem items that can be scored by parents of children aged 1–18 years. The items

refer to problem behaviors and emotions often encountered in children. A total problem score (comprising an internalizing and an externalizing score) is computed by adding scores for individual items. Subscores for aggressive behavior, anxious/depressed, attention problems, rule-breaking behavior, social problems, somatic complaints, thought problems, and withdrawn/depressed can also be calculated. The six DSM-oriented scales are affective problems, anxiety problems, somatic problems, attention deficit/hyperactivity problems, oppositional defiant problems, and conduct problems. The preschool 99-item version for 1.5–5-year-olds also has a DSM-oriented scale for autism/“pervasive developmental disorder.” Several studies have shown that combinations of subscales and individual items on the CBCL have good sensitivity and specificity for ASD in school-age children. In addition to the CBCL for parent rating, there is a related Teacher’s Report Form (TRF) and a Youth Self Report (YSR) for 11–18-year-olds.

Each item on the CBCL is given the same weight in the scoring system. The various subscales have been developed on the basis of factor and principal component analytic studies, and the DSM-oriented scales have been developed on the basis of a combination of statistical and clinical studies. One of the problems with the factor analytic approach relates to the fact that many of the individual items are completely unrelated and clearly do not have the same clinical weight. In fact, it can be argued that the individual items represent 118 different problems and that the subscales, to a considerable extent, represent artificial statistically derived constructs that do not necessarily correspond to recognizable clinical entities (in spite of having been assigned names that would suggest a clear correlation between the research and clinical concept). This problem is not unique to the development of the CBCL (and related material) but applies equally to a number of other much used scales, including those with subscales or full scales designed for screening and diagnosis of autism, for example, the Strengths and Difficulties Questionnaire (SDQ) (Goodman 1999) and the Autism Spectrum Screening Questionnaire (ASSQ) (Ehlers and Gillberg 1993).

Signal Detection Models and Receiver Operating Characteristic (ROC)

Many diagnostic systems are used to distinguish between two classes of events, essentially “signals” and “noise,” or “diagnosis” and “no diagnosis.” For such systems, analysis in terms of the “relative (or receiver) operating characteristic” (ROC) of signal detection theory provides a fairly precise and valid measure of diagnostic accuracy. It is uninfluenced by decision biases and prior probabilities, and it puts the performances of diverse systems on a common, easily interpreted scale.

The ROC model applied to a diagnostic screening instrument with a wide range of possible scores (such as the CBCL, the SDQ, or the ASSQ) is best presented in a graph detailing the true positive rate (TPR = sensitivity) on the y-axis and the false positive rate (FPR = 1 minus specificity) on the x-axis. The best trade-off for diagnostic purposes is usually seen at the point where the TPR is highest and the FPR lowest, that is, at the inflection point on the curve. The value of TPR times FPR at this point represents the area under the curve (AUC). When the AUC approaches 1.0, the diagnostic precision of the screening instrument is excellent, but when it approaches 0.5, the precision is extremely poor. The use of the AUC concept as a measure in the evaluation of new diagnostic screening tools has become something of a “gold standard” in recent years.

Continuous Distribution Models

Many human traits, functions, or markers of functional systems can be construed as existing on a normal distribution scale which will be relatively smooth when the range of possible scores is large. “Abnormality” is often defined as a specified distance from the mean or median score of such a scale (e.g., ± 2 standard deviations from the mean or under or over the second/98%). A disease or pathological state can be construed as existing when the value of a marker for a biological or psychological function is below a specified level (such as in pathological shortness/“dwarfism” or intellectual developmental disorder/mental retardation) or above a set limit (such as in hyperthyroidism).

Much can be said for diagnosing a number of psychiatric disorders along continuous distribution curves. Autism spectrum disorder (ASD), intellectual developmental disorder, and attention-deficit/hyperactivity disorder (ADHD) are but three examples of “disorders” that can, in many instances, be seen as extremes of “conditions” that exist along a normally/continuously distributed spectrum (Posserud et al. 2006). However, problems arise when it comes to specificity and determining exactly which specific trait should be considered the key marker function for the disorder. For instance, in ADHD, it is still not possible to determine whether attention, activity, or impulsivity aspects/functions should be considered core features of the “disorder.” Similarly, in ASD, it is not possible to assess the core quality of repetitive behaviors or, for that matter, perceptual functions, when it comes to delineating the “syndrome” of ASD. In the latter case – to “fully cover” the clinical spectrum of the “autistic state” in a given individual – it might be necessary to provide centile values for three or more continuous distribution curves, for example, empathy, central coherence, and rigidity-flexibility, and this would entail a great deal of conceptual and practical problems in clinical practice.

There are other problems with the continuous distribution model. First, it is as difficult to reasonably determine cutoff for abnormality under this model as it is in the general medical model of categorical disorders. Second, there are quite a number of instances, for instance, in ASD, when the model is totally inappropriate. It would not be correct or logical to categorize a case of autism caused by herpes encephalitis as being on a distribution curve shading into “normality.” Third, and not the least, there is a need for quick and dirty labels such as ASD and ADHD, much like there is a need for terms like “fever” and “pneumonia” (imprecise and even more vague terms than those used in neuropsychiatry). One of the most important features of a diagnostic label is its “door-opening” quality; by having a label, one will have easy access to knowledge. Having been given a percentage on a normal distribution curve, or worse, multiple different percentages on different curves will possibly be closer to “the

truth” but will often lead to more confusion than clarity. Having said this, the continuous distribution model has much to offer in second-level diagnostics: once a diagnosis of, for instance, ASD has been made, providing information about the individual’s level of functioning on a number of continuous distribution curves might actually help create a much more detailed (and holistic) view of that person’s functioning.

Current Knowledge

The DSM with a Particular Focus on Autism

As more and more research has documented the dimensional nature of so many core psychiatric disorders (including autism), the rigid structure and algorithmic nature of the DSM have come under increasing criticism. The inclusion of dimensional elements in the psychiatric diagnostic systems has been advocated for many years. However, it has been resisted due to concerns about clinical utility.

The categories in DSM are prototypes; a patient with a close approximation to the prototype is said to have that disorder. Each category of disorder has a numeric code taken from the ICD system, used for administrative purposes. One problem with this approach to diagnosis is that it does not properly deal with all those instances when a patient is severely impaired but does not meet *all* the criteria for a given discrete disorder. Every day in clinical practice (and in research), this is illustrated by diagnosis in the field of autism and related disorders. Many Western societies now have legislation specifically for autism. This means that having a “correct” diagnosis (i.e., one that fits with federal legislation) is extremely important. In needy clinical patients and in research prevalence studies, the categorical nature of the DSM system can be the arbiter between help and no help in terms of service provision and between case and noncase in epidemiological studies.

The way in which authors have articulated the multiple manifestations of autism has differed over time. Progress has been made in recent years, and this has brought about a convergence

on a shared definition of autism, including methods of assessment that are acceptable to workers from clinical and research centers across the world. Structured interviews (e.g., the DISCO-11, the ADI-R, and the ASDI) and observation schedules (including the ADOS-G) have brought organizational focus to the traditional psychiatric interview and developmental assessment. Such methods have provided a stricter format and directions to the interviewer, which, in turn, have enabled systematic assessment of *all* the criteria necessary for a diagnosis according to the given diagnostic (e.g., DSM) system. Having a consensually shared set of diagnostic criteria as well as structured assessment devices has helped ensure a more common unit of analysis in clinical practice and research across the globe. Though most workers would consider the operationalization of diagnostic criteria as an advance in psychiatry and developmental medicine, there remain concerns about the impact that the quest for increased diagnostic reliability might have on validity.

Current Clinical Practice and Research Use of the DSM

The DSM is primarily concerned with the symptoms and behavioral manifestation of mental disorders. With the exception of a small number of disorders (including “reactive attachment disorder”), it does not generally attempt to analyze or explain the conditions included in the manual.

The DSM-IV organizes each psychiatric diagnosis into five levels (axes) relating to different aspects of disorder or disability. Appropriate use of the DSM diagnostic criteria requires extensive clinical training, and its contents cannot be applied in a cookbook fashion. There is a risk that patients and nonmedical professionals may use the DSM in a checklist fashion and make “diagnosis” according to number of checked symptoms. It needs to be stressed that the DSM is a manual for medical psychiatric diagnosis. In practice, this means that it can only be used by highly skilled professionals making a definitive clinical diagnosis (i.e., medical doctors with specialist training in psychiatry and for some

disorders, including autism, ADHD, DCD, etc., those with training in neurology and developmental medicine).

Other, highly skilled, professionals use the DSM in clinical research. However, research diagnoses should not uncritically be equated with clinical diagnoses, and if a psychiatrist or other specifically trained medical doctor has not been involved in the diagnostic process, the “DSM diagnosis” should not be considered a psychiatric or medical diagnosis.

The DSM-5 published proposed diagnostic criteria in 2010 and revised proposed criteria in 2011. There was opportunity for specialists and the general public to react to these, and criteria were revised in the process. Once this was accomplished, the criteria were then tested in field trials. The results of these trials are not at hand at the publication of this volume.

Although the DSM-5 may move away from this categorical approach in some limited areas, some argue that a fully dimensional spectrum or complaint-oriented approach would better reflect the evidence (Krueger et al. 2005). Nevertheless, it is very difficult to envisage an overall change leading to fully dimensional diagnostics in psychiatry, given that it would not only be very difficult in practice but that it would entail a break with the tradition of categorical medical diagnosis that has a history of thousands of years.

Alternative Diagnostic Categories and Systems

Multiple Complex Developmental Disorder (MCDD)

The concept of MCDD was introduced by Donald Cohen (Towbin et al. 1993) in an attempt to “define and validate criteria for an early onset, chronic syndrome of disturbances in affect modulation, social relatedness, and thinking.” This syndrome, combining elements of autism, psychosis, and affective disorder, was considered possible to delineate and to be related to earlier onset of symptoms, very poor social and overall functioning, often long periods of inpatient treatment, and poor outcome.

Deficits in Attention, Motor Control, and Perception (DAMP)

The concept of DAMP was introduced by I Carina Gillberg (1987). It refers to the combination of problems in the domain of attentional abilities and motor-perceptual capacities in individuals who do not meet criteria for cerebral palsy. She and her colleagues had researched the clinical concept of minimal brain dysfunction (MBD) for a long time and had found that children thus diagnosed usually had this particular combination of problems (referred to as “perceptual, motor, and attentional deficits” as early as 1982). In later publications (e.g., Kadesjö and Gillberg 1999; Rasmussen and Gillberg 2000), DAMP was seen to correspond to the combination of ADHD and DCD. Gillberg (1983) noted that “severe” DAMP was strongly associated with marked autistic features and found that a large proportion of those diagnosed with “DAMP with autistic features” (=ADHD + DCD + autistic traits) actually met full diagnostic criteria for Asperger syndrome.

Disorders of Empathy

In the early 1990s, Gillberg launched the label of disorders of empathy and suggested that empathy and theory of mind were concepts that referred to closely related or perhaps even identical human functions (Gillberg 1992). He also proposed the concept of an empathy quotient (EQ) that might be used in a fashion similar to IQ when thinking about how ASD and related disorders could best be delineated from each other, from autistic traits and so-called normality. It was envisaged that a battery of tests of empathy including precursors of and mature-level theory of mind (and possibly subtests of facial recognition, central coherence, and set-shifting) would be developed so that disorders within the field could be diagnosed along a scale where an EQ of 70 might be set to demarcate cutoff for milder disorders (including that associated with the “Asperger phenotype”) and an EQ of 50 for more severe disorders (including the phenotype of “classic autism”).

Unfortunately, even though progress has been made regarding the understanding of the relationship between theory of mind, central coherence, executive function, and various types of disorders,

no “IQ-similar” EQ-test battery has been developed over the past two decades. Nevertheless, the concept of disorders of empathy (with autistic traits blending into “normality”) has gained considerable theoretical support over the last 20 years. It is still envisaged that having access to a test battery covering the basic functions and dysfunctions that have been shown to be clearly related to autistic symptoms would be extremely helpful and would pave the way for a “real” alternative ASD diagnostic system, clearly conceptually different from the one that will still be espoused in the DSM-5.

Nonverbal Learning Disability

The concept of nonverbal learning disorder or disability was introduced in a book by Rourke in 1988 and in an influential paper in 1989 (Rourke et al. 1989). The “diagnosis” – which is not in any of the official diagnostic manuals – rests on a considerable discrepancy between verbal and nonverbal skills on tests in individuals who are relatively proficient in expressive language skills. Affected individuals are often motor clumsy, perceptually abnormal, socially awkward, “dyspraxic,” and with poor pragmatic skills (in spite of sometimes superior formal verbal skills). Rourke has suggested that the overlap between nonverbal learning disability and ASD/Asperger syndrome is substantial.

Early Symptomatic Syndromes Eliciting Neurodevelopmental Clinical Examinations (ESSENCE)

The ESSENCE concept was introduced by Gillberg (2010). The acronym refers to early symptomatic syndromes eliciting neurodevelopmental clinical examinations. Gillberg coined this acronym with a view to alerting clinicians and researchers to the reality of a very large number of children (and their parents) presenting in clinical settings with impairing, persistent symptoms before age 3 (to 5) years – symptoms that will endure and overlap for many years, usually into adulthood – in the fields of (a) general development, (b) communication and language, (c) social interrelatedness, (d) motor coordination, (e) attention, (f) activity, (g) behavior, (h) mood, and/or (i) sleep. Children with major difficulties in one or more (usually several) of

these fields, will be referred to and seen by health visitors, nurses, social workers, education specialists, pediatricians, GPs, speech and language therapists, audiologists, child neurologists, child psychiatrists, psychologists, neurophysiologists, dentists, clinical geneticists, occupational therapists, and physiotherapists. Usually they will be seen only by one of these specialists, when they would have needed the input of two or more of the experts referred to. Major problems in at least one ESSENCE domain before age 5 years usually signal major problems in the same or overlapping domains years later. "There is no time to wait; something needs to be done, and that something is unlikely to be just in the area of speech and language, just in the area of autism or just in special education."

ESSENCE is not a new proposed diagnosis but represents an alternative way of approaching the problem of diagnosis in "child neuropsychiatry" and "developmental medicine." At very young ages, children with developmental problems present for diagnosis in a variety of settings, and depending on the type of specialist in charge, one or another of the many possible diagnoses contained in the ESSENCE basket is likely to be made (or not made for that matter). The risk is obvious that only the diagnosed problem type will be intervened for (or that the child excluded from, say, the autism category will not be worked up for his/her very real ADHD and hence excluded from relevant therapy). ESSENCE may be the "only safe label" at an early age. However, ESSENCE is not a diagnosis but a reminder that the child with that "label" will, sooner or later, have one, two, three, or even more diagnoses made. ESSENCE is a label that acknowledges the universal coexistence of symptoms and problems across diagnostic borderlines. All the problems need to be addressed, not just those associated with one discrete diagnostic category.

Future Directions

The DSM-5 and the ICD-11

Major attempts are being made to streamline the DSM-5 and the ICD-11. Several of the personality disorder categories will be gone from the DSM-5,

and a few new categories of psychiatric disorder will be included. It is expected that autism will become one category (no longer referred to as pervasive developmental disorder but, most probably, "autism spectrum disorder") and that subgrouping will be done on the basis of a number of "nonautism" demographics such as level of IQ, language competence, and severity.

Comorbidity and the DSM System

The term "comorbidity" was introduced in medicine to denote those cases in which a "distinct additional clinical entity" occurred during the clinical course of a patient having an index disease. This term has recently become very fashionable in psychiatry and developmental medicine to indicate not only those cases in which a patient receives both a psychiatric and a general medical diagnosis (e.g., autism and tuberous sclerosis) but also those cases in which a patient receives two or more psychiatric diagnoses (e.g., autism and Tourette syndrome). Gillberg (1983) pointed to this overlap of "discrete" psychiatric diagnoses in young children long before the word "psychiatric comorbidity" came into common parlance. The co-occurrence of two or more psychiatric diagnoses has been reported to be very frequent. For instance, in a general population study, 85% of young children with ADHD had at least one additional DSM diagnosis leading to impairment (Kadesjö and Gillberg 2001). In the case of severe autism, it is virtually impossible to find one single case in which there was no other mental or physical disorder. If a diagnosis of autistic disorder according to the DSM-IV-TR is made, one would have to be on the lookout for intellectual developmental disorder/mental retardation/learning disability, epilepsy, a medical disorder such as tuberous sclerosis or 22q11 deletion syndrome, neuropsychiatric disorder such as Tourette syndrome or ADHD, mood disorder, anxiety disorder, eating disorder, sleep disorder, or a specific developmental disorder such as developmental coordination disorder (DCD). There is a further diagnostic problem stemming from the fact that a majority of these other named disorders have a large subgroup with ASD, that the symptoms of all the disorders first appear and

overlap at a very early age, and that it can be very difficult to decide from the start which of the problem types is going to be the “main diagnosis,” that is, the one (or the ones) that will warrant intervention. The acronym ESSENCE has been introduced in order to draw attention to this state of affairs (Gillberg 2010).

The co-occurrence of multiple registered psychiatric diagnoses is now common. This is to some extent due to the use of standardized diagnostic interviews, which helps to identify several clinical aspects that in the past remained unnoticed after the principal diagnosis had been made. Fragmenting a complex clinical condition into several pieces may prevent a holistic approach to the individual.

An obvious determinant of the emergence of the phenomenon of “psychiatric comorbidity” (see below) has been the proliferation of diagnostic categories in recent classifications. If demarcations are made where they do not “really” exist, the probability that several diagnoses have to be made in an individual case will obviously increase.

A coveted tradition in psychiatry and developmental medicine has been to establish a hierarchy of diagnostic categories so that, for example, if autism were present, the possibly concomitant anxiety, depression, or ADHD would not be diagnosed because they would be regarded as part of the clinical picture of autism.

Because everyone has now been using operationalized diagnostic criteria for three decades or more, diagnoses such as autistic disorder have, by some, come to be regarded as more reliable than traditional clinical diagnoses. The old clinical descriptions provided a gestalt of each diagnostic entity. Different emphasis was put on the various clinical aspects, whereas current operational definitions usually give equal weight to a variety of clinical manifestations, *counting* symptoms rather than *weighing* them. Traditional clinical assessment demanded arbiter differential diagnosis, whereas current operational definitions really open up for multiple diagnoses (even though the DSM-IV often actively resists this), possibly in part because they are less able to convey the “essence” of each diagnostic entity.

Along with the trend as regards reliance on operationalized algorithms for diagnosis, has emerged a new insistence on “specific” instruments for these checklist categorical disorders. This is particularly true in autism, where both clinicians and researchers have been overtaken by an industry of diagnostic interviews and observation schedules that purportedly increase the quality of the (single) diagnosis *per se*. It is important to remember that these instruments were developed on the basis of studies using gold standard clinical diagnosis and that they will never, in themselves, be better than such diagnoses. It is envisaged that the heyday of these instruments will be over in the next few years and that they will be replaced by measures more accurately acknowledging and reflecting the developmental and overlapping nature of the conditions in question.

The frequent co-occurrence of the mental disorders has been taken as evidence against the idea that these disorders represent discrete disease entities (Cloninger 2002). The point has been made that psychopathology is usually complex and variable and that what is currently conceptualized as the co-occurrence of multiple disorders could be better reformulated as the complexity of many psychiatric conditions (with increasing complexity being a predictor of greater severity, disability, and service utilization). Even Kraepelin, in one of his later works, dismissed the model of discrete disease entities even for dementia praecox and manic-depressive disorder (Kraepelin 1920).

However, an alternative possibility is that psychopathology does consist of discrete entities, but these entities are not well delineated by current diagnostic categories. If this is the case, then current clinical research on “psychiatric comorbidity” may be helpful in the search for “true” disease entities, contributing in the long term to a rearrangement of present classifications.

There is, of course, another possibility, namely, that the nature of psychopathology is intrinsically heterogeneous, consisting partly of disease entities and categorical disorders, and partly of maladaptive response patterns or of exaggeration of traits that are more or less normally distributed in the general population.

ASD in the DSM-IV and the DSM-5

The DSM-IV comprised of five different autism spectrum disorder categories. The DSM-5 contains only one autism category, incorporating autistic disorder, Asperger's disorder, childhood disintegrative disorder, and PDDNOS into one common coded condition referred to as "ASD" (and leaving, reasonably, Rett syndrome out of the equation).

The change reflects increasing awareness that much of the DSM-IV subgrouping of autism was based on attitudes and personal stance rather than empirical evidence. For instance, most systematic studies have not found support for a clear distinction between autistic disorder and Asperger's disorder. It is also unclear to what extent CDD should be seen as different from autistic disorder with regression, and whether or not "mild" or highly atypical cases of PDDNOS are really related to autistic disorder at all.

There are only seven symptoms in the proposed DSM-5 as compared with 12 in the DSM-IV. There are only two subgroups of symptoms rather than three. The change in number of symptoms superficially gives the impression of a major reconceptualization of the whole category. However, on closer inspection, what has been achieved is a pruning of several symptoms that were felt by many to be vague and relatively unimportant or to be hallmarks of other conditions (such as severe learning disability or severe expressive language disorder), a collapsing of some of the remaining ones, and the addition of a behavioral criterion of perceptual abnormality. Also, the social and communication categories have been collapsed into one. This mirrors the now generally accepted notion that at the root of both the social and communication problems in autism is a shared deficit in intuitive understanding of the meaning of reciprocity. Finally, the three specific social-communication symptoms in the DSM-5 must all be met for a diagnosis to be considered (compared to only two out of four in the DSM-IV), and there must be at least five of the seven total number of symptoms met (compared to "only" 6 of the 12 autistic disorder criteria in the DSM-IV). The age criterion has been changed from delay or abnormal functioning being evident

before age 3 years (DSM-IV) to symptoms having been present from early childhood (DSM-5).

Taken together, it would seem that the proposed DSM-5 might actually restrict somewhat the number of cases of autistic disorder meeting full criteria for autism spectrum disorder compared to the DSM-IV. Also, many of the cases meeting Asperger's disorder symptom criteria (only three symptoms in total needed in the DSM-IV) and PDDNOS "criteria" (that are really extremely vague) would probably fall short of diagnostic status under the DSM-5. The Gillberg's Asperger syndrome category would, on the other hand, at least at a glance usually meet criteria for ASD under the DSM-5. However, all of this is, of course, pure speculation at the present time. Changing the diagnostic criteria, as with the introduction of the DSM-5 (ICD-11), will definitely lead to changes in numbers of cases diagnosed. This, in the case of autism, will, almost certainly, lead to claims of "autism epidemics" or "autism disappearing" in the headlines of many major newspapers from about 2015 onward. This is the extent of what can be reasonably predicted as a result of the introduction of the new diagnostic manuals.

Alternative Diagnostic Systems

MCDD

The following diagnostic criteria for MCDD (or multiplex developmental disorder) have been suggested by the Yale Autism Study Group: (1) *impaired social behavior/sensitivity, similar to that seen in autism*, such as (a) social disinterest, (b) detachment, avoidance of others, or withdrawal, (c) impaired peer relations, (d) highly ambivalent attachments, (e) limited capacity for empathy or understanding what others are thinking or feeling; (2) *affective symptoms*, including (a) impaired regulation of feelings, (b) intense, inappropriate anxiety, (c) recurrent panic, (d) emotional lability without obvious cause; (3) *thought disorder symptoms*, such as (a) sudden, irrational intrusions on normal thoughts, (b) magical thinking, (c) confusion between reality and fantasy, (d) delusions such as paranoid thoughts or fantasies of special powers.

A few studies have tried to examine the relative proportion of MCDD cases within the broader category of ASD. They have found the “condition” to be rare, accounting for fewer than one in ten of all relatively high-functioning cases (Sturm et al. 2004).

It is clear that the combination of problems subsumed under the MCDD heading exists in a small number of individuals and that those affected are very severely impaired. However, studies that have attempted to separate out children with MCDD from those with other “variants” of PDD or schizophrenia have usually not been able to clearly differentiate them from those with other diagnoses. Nevertheless, MCDD, if it will remain as an alternative category, is a diagnostic label that will only be applied in a limited number of patients presenting with ASD symptomatology. In some ways, it resembles the DAMP concept (see below) in that it could possibly be categorized as the concomitant presence of two “discrete” disorders, namely, ASD and schizophreniform disorder.

DAMP

DAMP, when defined as the combination of ADHD and DCD, is a common clinical problem (affecting several percent of all school-age children) that has well-documented ramifications both as regards need for intervention and prognosis (Rasmussen and Gillberg 2000). There are about 50 publications in the scientific literature. Stimulant treatment, cognitive behavioral therapy, special education measures, *and* occupational therapy are likely to be needed in any intervention program. Autistic features are very common and may need special approaches, and there is usually a speech and language component to be taken into account when designing the intervention plan. DAMP has been an accepted alternative clinical diagnostic concept in the Scandinavian countries for many years. However, given its literal meaning when read out as a word rather than as an acronym, it is unlikely that it will become generally accepted as an internationally used diagnostic concept. However, the insight into the common comorbidity

of ADHD with DCD (and of these two problem types with ASD) and the gradually growing awareness among clinicians that DCD is often a problem that should be treated “in its own right” will probably lead to acceptance of the importance of the underlying construct.

Disorders of Empathy

The gradual refinement of concepts such as self-initiated joint attention, theory of mind, central coherence/local-global processing and “connectivity,” facial emotion-recognition, mirror-neuron functions, and certain executive functions (including set-shifting) will possibly pave the way for development of age normed EQ tests that will allow a dimensional approach to diagnosis within the empathy spectrum disorders (or, using another term, ASD). Again, it is possible that the word empathy in itself might be seen by some to be too provocative, seeing as it has come to be associated with a positive (emotional) value (even though this was not its original meaning when the word was coined over a century ago). It could be that “disorders of social communication” will be a preferred term. Even so, it is likely that the concept of EQ (or SCQ, social communication quotient) will get rooted and upon up new avenues of diagnosing autistic traits across a range of problem types, just as the concept of IQ has come to be accepted as something useful when considering any type of problem, regardless of “other diagnoses.”

Nonverbal Learning Disability

One of the problems with the concept of nonverbal learning disability is that there does not seem to be any consensus regarding how it should be diagnosed. Most published studies have relied on results of IQ testing (often with one of the Wechsler scales), and the diagnosis has been made in cases with a verbal IQ that is 15 points (or 15–20% in some studies) higher than performance IQ. However, other authors, including Rourke, would instead use variations on the following diagnostic algorithm: a nonverbal learning disability refers to a subtype of learning-disabled children who have outstanding deficits in interpersonal relationships,

visual spatial organization, organization and planning skills, flexible concept formation, study skills, specific academic areas, and social judgment.

Several studies have attempted to delineate the boundaries between nonverbal learning disability on the one hand and Asperger syndrome on the other. One study has found a very high rate of nonverbal learning disability in young boys with Asperger syndrome; in fact, at least half of all young males with the syndrome had the typical verbal-nonverbal discrepancy (Cederlund and Gillberg 2004). However, when the same individuals were followed up in adult age, only one in five had clear test results indicating persistence of such a discrepancy, meaning that at least half of all those who had childhood indicators had “grown out” of “test evidence” of nonverbal problems after adolescence. Some studies have found no indication of a link between the “neuropsychological disorder” and the clinical syndrome of Asperger.

ESSENCE

It is likely that ESSENCE – or a similar concept – will become influential over the next several years. As has already been pointed out, ESSENCE is not in itself a diagnosis but a broader category covering a variety of neurodevelopmental, psychiatric, and neurological conditions that are sometimes behavioral phenotypes with a known etiology, sometimes empirically derived symptom clusters related to neuronal dysfunction, and sometimes the extreme on curves of normally distributed traits in the general population.

The term ESSENCE acknowledges the very common existence of such conditions and the fact that they are almost always “comorbid” with each other, that the comorbidities (and, indeed, the “main diagnosis”) may vary over time, weave in and out of each other, and that therefore the clinical picture tends to vary with age and time. ASD is but one category (or endpoint on a dimensionally distributed set of traits) within ESSENCE. ASD is virtually never an individual’s *only* problem; there is perhaps *always* an additional impairment that warrants clinical diagnosis and

intervention (including ADHD, tics, depression, anxiety, anorexia nervosa, an associated medical condition, epilepsy, DCD, cerebral palsy, hydrocephalus, catatonia, hyperlexia, dyslexia, speech and language disorder, intellectual developmental disorder, nonverbal learning disability). ESSENCE also flags up the possibility that ASD (or ADHD, tics, etc.) may not be the major clinically impairing problem throughout a person’s life that it can become less impairing with time (to the point that the need for a clinical diagnosis may be called into question) but that other so-called comorbidities (such as ADHD, depression, DCD, intellectual developmental disorder) may be seen as much more impairing and could, in fact, be main drivers of a poor outcome.

It is envisaged that over time, ESSENCE clinics, rather than (“overspecialized”) autism clinics, will be seen as the way forward. Children, adolescents, adults, and their families with one or more (usually several) of the problem types subsumed under the ESSENCE acronym (and remember that in many “ASD cases,” there is not only ESSENCE “comorbidity” in the individual referred for diagnostic workup but one or more of close relatives will also have ESSENCE problems) will need good diagnostic workup and intervention for *all* impairing problems, not “just” for ASD. This is not to say that good autism diagnostics and focused autism intervention will not be needed – quite the opposite – but that the strong emphasis on autism as a unique and separate syndrome may lead to inadvertent, underdiagnosis, and undertreatment of associated, highly treatable ESSENCE problems.

Amantadine

Fred R. Volkmar

Child Study Center, Irving B. Harris Professor of Child Psychiatry, Pediatrics and Psychology, Yale Child Study Center, School of Medicine, Yale University, New Haven, CT, USA

Definition

This drug (known as 1-adamantylamine or 1-aminoadamantane) was first approved by the FDA in 1966 for the treatment of influenza; its effectiveness for the treatment of symptoms of Parkinson's disease and drug-induced movement problems (extrapyramidal effects and akathisia) was discovered accidentally. For the treatment of Parkinson's disease, it is used alone or in combination with other agents. The efficacy of its use for Parkinson's disease has been questioned in a recent review (Crosby et al. 2003). Because of growing resistance, it is not now recommended for use in influenza treatment.

There appear to be several mechanisms of action since the agent impacts multiple brain neurotransmitter systems. Central nervous system side effects include anxiety, agitation, and increased seizure activity. Other side effects have included skin problem and suicidal thoughts.

The drug has been used without FDA approval for various other purposes including in autism. In the largest study, King et al. (2001) treated a group of children and adolescents with amantadine using both parent- and clinician-based report measures in a placebo-controlled study. They noted a large placebo effect overall with clinician ratings but not parent ratings suggesting some possible benefit of the agent over placebo. Amantadine was well tolerated. The drug remains one of many agents that deserve study in autism.

American Academy of Clinical Neuropsychology (AACN)

Linus A. Bieliauskas

Department of Psychiatry (F6248, MCHC-6), University of Michigan Health System, Ann Arbor, MI, USA

Membership as of 5/13/20: 1,087 Active, 75 Senior, 643 Affiliate, and 183 Student members.

Mission Statement: AACN is the organization for those psychologists who have achieved board certification in the specialty of Clinical Neuropsychology, by the American Board of Clinical Neuropsychology (ABCN), under the auspices of the American Board of Professional Psychology (ABPP). Board Certification covers neuropsychological aspects of brain-behavior disorders in children, adults, and the elderly. AACN supports continued maintenance of standards in Clinical Neuropsychology through the established board certification process of ABCN. AACN supports the continued development of the ABCN examination process, and advocates for the standards represented by board certification. In addition, Child Subspecialty Certification was added in 2014. Individuals wishing to obtain this certification need to be board certified through ABCN, fill out an added application form, take an added written exam, and undergo an added practice sample review.

Major Activities: AACN has an annual meeting open both to members and nonmembers. The meeting includes an extensive continuing education program which will be of interest to all, including special courses for candidates for board certification and for AACN members and others to maintain specialty knowledge. *The Clinical Neuropsychologist* is the official journal of AACN. In addition to copies of AACN policy statements which can be accessed via the link, <https://www.tandfonline.com/toc/ntcn20/current>, *The Clinical Neuropsychologist* publishes all AACN official policies and documents. AACN also includes the journal *Child Neuropsychology* for all of its members.

American Academy of Neurology

Miya Asato
Pediatrics and Psychiatry, Division of Child
Neurology, School of Medicine, Children's
Hospital of Pittsburgh, University of Pittsburgh,
Pittsburgh, PA, USA

Major Areas or Mission Statement

American Academy of Neurology (AAN)
1080 Montreal Avenue
Saint Paul, MN 55116
(800) 879-1960
www.aan.com
Child Neurology Society (CNS)
1000 W. County Road E, Suite 290
Saint Paul, MN 55126
(651) 486-9447
www.childneurologysociety.org

The AAN is an international professional association of over 22,000 neurologists and neuroscience professionals dedicated to promoting neurologic care. Members include both adult and child neurologists. The AAN is the primary professional society for clinical neurologists. It is dedicated to maintaining awareness among its membership of clinical and scientific advances

that impact clinical care and to providing educational opportunities for maintaining the knowledge and skills of its members. The AAN also commissions subcommittees to develop practice guidelines that disseminate the state of the science on specific clinical issues that confront neurologists in their daily practices.

The CNS is a professional association of pediatric neurologists and developmental pediatricians in the United States, Canada, and worldwide devoted to optimizing the care of children with neurological and neurodevelopmental disorders. There are over 1500 members. Like the AAN, the CNS has an annual meeting with a program designed to disseminate the latest scientific and clinical advances related to child neurology and to maintain the skills and knowledge of its clinicians. The CNS provides practice guidelines, maintenance of certification support, and CME programming in child neurology and developmental pediatrics, including autism.

The AAN and CNS are dedicated to promoting the highest quality patient-centered neurologic care and enhancing member competence and career satisfaction.

Major Activities

The AAN and CNS provide scientific and clinical education for its members in many formats, commission the development of practice guidelines to support improved standards of care, and public leadership and advocacy for individuals impacted by neurologic and neurodevelopmental disorders. Both organizations have provided educational sessions and practice guidelines on autism and on many related/overlapping issues (see “► [Reading](#)” for examples).

American Academy of Pediatrics

Susan Hyman
Developmental and Behavioral Pediatrics,
Division Chief Neurodevelopmental and
Behavioral Pediatrics, University of Rochester
Golisano Children's Hospital, Rochester,
NY, USA

Major Areas or Mission Statement

Membership as of August 2017: Approximately 66,000 members in the United States, Canada,

Mexico, and internationally including pediatricians, pediatric subspecialists, and surgical subspecialists belong to the American Academy of Pediatrics (AAP). Thirty-four thousand members are Board Certified in Pediatrics and can be listed as Fellows of the American Academy of Pediatrics or FAAP.

Major Areas or Mission Statement: “The mission of the AAP is to attain optimal physical, mental, and social health and well-being for all infants, children, adolescents, and young adults. To accomplish this mission, the AAP shall support the professional needs of its members.”

Landmark Contributions

Landmark Contributions: It was not until the late 1800s that the care of children began to emerge as a separate area of specialization within medicine. The recognition that growth and development, nutrition, and prevention of infectious diseases in increasingly urbanized communities required focused research led to the founding of the American Pediatric Society in 1888. The increasing number of physicians who limited their practices to the primary care of children in office settings resulted in the formation of the American Medical Association section on pediatrics in 1880. Proposed federal legislation to provide matching funds to states for infant welfare clinics was supported by the American Medical Association section on pediatrics in 1922, but not the leadership of the American Medical Association who saw it a potential initial step to socialized medicine. The commitment by physicians who cared for children to advocate for the welfare of children led to the formation of an independent organization, the American Academy of Pediatrics, in 1929. The original 35 members met in Detroit to establish a professional organization that recognized that the needs for disease prevention and health promotion in children were different than those for adults. In 1930, there were 304 members.

The AAP set out to support and develop the field of pediatrics. The *Journal of Pediatrics* began publication in 1932 and was the official journal until *Pediatrics* assumed that status in

1948. In collaboration with the American Pediatric Society and the AMA section on pediatrics, the AAP supported development of the American Board of Pediatrics in 1934 as an independent organization to establish formal training criteria and certification of expertise in the specialty of pediatrics as well as to approve and certify subspecialists within pediatrics. Specialists and subspecialists must now demonstrate an ongoing commitment to professional education and incorporate quality improvement into their practices to maintain certification.

The AAP has major initiatives regarding the education of professionals and of the public on disorders of childhood in addition to advocacy for the health and well-being of children and families including areas as diverse as disease prevention, behavioral health, education, and the environment. Publications such as the *Red Book* guide practice related to immunization and management of infectious diseases. The efforts of the AAP have been critical in the passage of legislation such as supporting health insurance for children (SCHIP) and Head Start. The policies and recommendations of the AAP guide the health care provided to children by pediatricians and serve to advise other organizations and agencies. In addition to the headquarters in Elk Grove Village, Illinois, it maintains an office in Washington, DC.

Major Activities

The AAP's major activities address member education, public education, advocacy for children and youth, and promotion of community-based research and demonstration projects.

Organization: The AAP is divided into 10 regional districts and 59 state chapters each with elected officials who represent the chapters in the national organization. It is also organized by interest areas within pediatrics into 13 councils and 52 sections. Twenty-seven committees advise the elected leadership of the AAP in the development of the AAP's positions and programs. Committees have interests as varied as injury and poison prevention, children with disabilities, sports medicine, nutrition, and child health financing.

Activities related to autism are primarily managed by the Council on Children with Disabilities, and its Autism Subcommittee, and the Section on Developmental and Behavioral Pediatrics. Other groups with specific interests related to autism include the sections on General Pediatrics in Office Settings, Complementary, Holistic, and Integrative Medicine; Genetics; Gastroenterology, Hepatology, and Nutrition; Injury, Violence, and Poison Prevention; and Neurology and the Council on Environmental Health.

Education: The AAP coordinates continuing education courses, annual scientific meetings, seminars, and online education for pediatricians to address ongoing educational needs. It publishes the journal *Pediatrics* to promote academic understanding of the health needs of children and youth. It also publishes *Pediatrics in Review* as a journal for continuing education, *AAP News* as a member's news magazine, and manuals on topics important to child health such as infectious diseases and school health. Books are written for families on topical areas such as toilet training, Attention Deficit Hyperactivity Disorder, and others. Brochures on many areas relevant to child health, development, behavior, and safety are available to pediatricians to provide information to their patients. To assist child health professionals and policy makers, the AAP committees prepare technical reports and policy statements to summarize current information for the providers and recommend health-care practices. Policies which recommend practice and clinical reports that summarize the medical literature are posted on the AAP website.

Publications related to autism include the informational brochures for families on autism and language delays published in 2007. That year, two clinical reports were published in *Pediatrics* on the assessment and the management of children with autism. Policies of related interest include developmental screening (2006), use of complementary and alternative medicine by children with chronic illness (2001), learning disabilities, dyslexia, and vision (2011). The Autism Toolkit was revised in 2012. A full listing is accessible at www.aap.org.

Public Education: Educational materials for families on common topics are published for

distribution in the context of anticipatory guidance in well-child care and as information related to specific concerns, as well as books on topics such as toilet training and ADHD. Web-based information for families is a priority of the www.healthychildren.org website.

Advocacy: The AAP has an office in Washington, DC that advocates at the federal level for children's health needs in emerging policies and legislation. AAP staff assist the state chapters of the AAP in state and local advocacy around issues such as child safety legislation, Autism insurance legislation, and insurance legislation that assure access to care for low-income children.

Research: Through the Pediatric Research in Office Settings (PROS) network and CATCH grant mechanisms, the AAP promotes research in the community that addresses health needs as well as program development. Interest areas include social, economic, and behavioral research in addition to provision of medical care and disease prevention.

American Association on Intellectual and Developmental Disabilities (AAIDD)

Marc J. Tassé¹ and Matthew Grover²

¹Nisonger Center – UCEDD, Departments of Psychology and Psychiatry, The Ohio State University, Columbus, OH, USA

²Otterbein University, Westerville, OH, USA

Major Areas or Mission Statement

The American Association on Intellectual and Developmental Disabilities (AAIDD) is an interdisciplinary professional society of members who have a professional focus in the area of intellectual and developmental disabilities. The AAIDD counts approximately 3,500 interdisciplinary professionals as its members. The membership structure includes professionals working in the field of intellectual disability and related developmental disabilities. Members can select from a tiered membership menu: basic, classic, standard, premium, and corporate. AAIDD is primarily a North

American professional association, but it also offers an “international” membership option and has international members from 55 countries. The corporate membership is available to centers or agencies who may join, garnering a reduction on membership dues for the employees affiliated with the corporate member.

Association members have the option of joining any of its 21 special interest groups (e.g., administration, education, psychology, health and wellness, criminal justice, etc.).

Mission Statement

AAIDD promotes progressive policies, sound research, effective practices, and universal human rights for people with intellectual and developmental disabilities.

AAIDD Has Adopted a 7-Point Set of Principles (or Core Values) Relative to Its Mission

- Cultivate and provide leadership in the field of intellectual and developmental disabilities that encompasses a diversity of disciplines, cultures, and perspectives.
- Enhance the skills, knowledge, rewards, and conditions of people currently working in the field and encourage promising students to pursue careers in the field of intellectual and developmental disabilities.
- Advance basic and applied research to prevent or minimize the effects of intellectual and developmental disabilities.
- Advance the assurance of all human rights of people with intellectual and developmental disabilities, including equality, individual dignity, choice, and respect.
- Promote genuine accommodations to expand participation in all aspects of life for people with intellectual and developmental disabilities, opportunities for choice and self-determination, and access to quality health, education, vocational, and other human services and supports.
- Influence positive attitudes and public awareness to contributions of people with intellectual and developmental disabilities.
- Establish partnerships and strategic alliances with organizations that share our values and goals.

AAIDD's Goals

1. Enhance the capacity of professionals who work with individuals with intellectual and developmental disabilities.
2. Promote the development of a society that fully includes individuals with intellectual and developmental disabilities.
3. Sustain an effective, responsive, well-managed, and responsibly governed organization.

Landmark Contributions

AAIDD was founded in 1876 and has since been the leader in setting the practice standards; publishing books, tests, and other resources; and influencing policy. AAIDD's first president in 1876 was the French physician Édouard Séguin, MD, regarded by many as the father of special education in the USA.

The AAIDD has led the field in establishing the definition and diagnostic criteria for intellectual disability for over a century. It is well established that a significant proportion of individuals with an autism spectrum disorder also have a co-occurring diagnosis of intellectual disability. Since its first definition of intellectual disability in 1910, AAIDD has revised its definition ten times to reflect the changes in research and understanding of this condition (currently in its 11th edition). The AAIDD definition of intellectual disability has historically been adopted by all federal and state governments as well as the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders* (DSM) in defining intellectual disability. AAIDD is considered the professional authority in the area of intellectual disability.

In examining the history of the AAIDD, one quickly discovers that the organization has undergone a number of changes since it was founded in 1876. The chief among these changes is the position of the organization with regard to issues such as (a) etiology of the disability, (b) systems of classification, and (c) systems of support/intervention. The AAIDD was founded by a small group of superintendents of institutions for people with disabilities. The AAIDD's first annual

meeting was held at the Pennsylvania Training School for Idiotic and Feeble-minded Children (now called Elwyn) in Media, PA, on June 6, 1876 (Sloan and Stevens 1976), where it was founded under the name of “Association of Medical Officers of American Institutions for Idiotic and Feeble-minded Persons” (Sloan and Stevens).

The Association’s first constitution provided a framework for the goals of the association during its earliest days (Sloan and Stevens 1976, p. 1):

Article II: The object of the association shall be the discussion of all questions relating to the causes, conditions, and statistics of idiocy and to the management, training, and education of idiots and feeble-minded persons; it will also lend its influence to the establishment and fostering of institutions for this purpose.

Although the association’s policies have evolved over time, the common goal of reaching a better understanding of intellectual disability and serving to improve the lives of people with intellectual disability has remained unchanged throughout the years.

Changes in the association’s name serve as somewhat of a barometer for the shifting attitudes toward people with intellectual disability within our society at large. The association name changes have largely been driven by a move away from historical terminology that has acquired increasingly pejorative connotations. In 1910, the name of the association was changed to “American Association for the Study of the Feeble-minded.” This was the first of the several name changes for the association. The name was changed again in 1933 to “American Association on Mental Deficiency” (AAMD), which remained until 1987, when it officially became known as the “American Association on Mental Retardation.” The most recent change came in 2007, bringing with it the current name “American Association on Intellectual and Developmental Disabilities.” This change was driven by the increasing acceptance of “intellectual disability” as the replacement terminology for mental retardation. AAIDD also chose to include “developmental disabilities” in its name to reflect its mission and influence in areas such as autism spectrum disorder, cerebral palsy, and other related developmental disabilities.

A landmark change brought about by AAIDD was in 1959 when it introduced the construct of adaptive behavior into its definition of intellectual disability (Heber 1959). The 1959 AAIDD terminology and classification manual first introduced deficits in adaptive functioning as part of the diagnostic criteria for intellectual disability. All other major diagnostic systems (e.g., World Health Organization’s International Classification of Diseases, American Psychiatric Association’s *Diagnostic and Statistical Manual of Mental Disorders*) as well as federal and state agencies followed suit. AAIDD also published the first standardized measure of adaptive behavior in 1969 – titled the AAMD Adaptive Behavior Scale (Nihira et al. 1969).

AAIDD has long been active in influencing legislation and social action toward improving treatment and supports for people with intellectual and developmental disabilities.

Throughout the years, AAIDD has served as *amicus curiae* in many cases regarding the rights of people with intellectual disability (Croser 1999; Herr 1999). James W. Ellis, JD, a Professor of Law at the University of New Mexico and past president of AAIDD, successfully argued before the US Supreme Court (*Atkins v. Virginia* 2002) that the execution of people with ID was cruel and an unusual punishment. The *Atkins v. Virginia* Supreme Court ruling led to the banning of capital punishment for all people diagnosed with ID and upheld in two subsequent Supreme Court decisions (e.g., *Hall v. Florida* 2014; *Moore v. Texas* 2017). AAIDD was prominently mentioned in the 2002 *Atkins v. Virginia* as well as both follow-up Supreme Court decisions as a leading national organization in setting the national consensus regarding the definition and diagnosis of intellectual disability.

Major Activities

The association offers a wide array of trainings, including an annual professional meeting. AAIDD publishes books, journals, assessment instruments, and training materials. Among its publications, AAIDD publishes two of the mostly

highly cited professional journals in the field of disabilities: *American Journal on Intellectual and Developmental Disabilities* and *Intellectual and Developmental Disabilities*. Many of its publications have been translated into dozens of languages and are disseminated and used worldwide.

American Board of Genetic Counseling

Erin Loring

Yale Department of Genetics, New Haven, CT, USA

Major Areas or Mission Statement

American Board of Genetic Counseling (ABGC)

Mission Statement

The American Board of Genetic Counseling establishes standards of competence through accreditation of graduate training programs and certification and recertification of genetic counselors to advance the profession and protect the public.

Membership

Currently there are 3,026 ABGC Certified Genetic Counselors.

The American Board of Genetic Counseling is a nonprofit organization incorporated in 1993 as the accrediting and credentialing body for the genetic counseling profession. The ABGC credential, Certified Genetic Counselor (CGC®), identifies counselors who have met established standards for graduate training with practical clinical experience, passed a comprehensive genetic counseling board examination, and demonstrate a commitment to maintain knowledge through recertification. The ABGC credentials have become recognized as the gold standard in the health care industry.

The ABGC organization is led by ten elected board members who serve a 5-year term. Board

members along with ABGC diplomates run committees, volunteer as item writers, and supervise genetic counseling training programs.

Landmark Contributions

The first genetic counseling training program graduated its master's-level genetic counselors in 1971. Since 1981, the American Board of Medical Genetics (ABMG) had been the body responsible for the certification of genetic counselors. A decade later, the American Board of Medical Specialties recognized genetics as a medical specialty and offered the ABMG an invitation to join. A condition of the membership was that the ABMG was required to exclude non-doctoral-level candidates from its certification process. An agreement was made for the formation of the ABGC. On October 23, 1992, the American Board of Genetic Counseling was incorporated to be the new accrediting and credentialing body for the genetic counseling profession.

The ABGC saw the opportunity to restructure the accreditation guidelines and the overall approach to accreditation. After carefully examining the accreditation practices of other specialties, it elected to accredit entire genetic counseling programs instead of only clinical training sites as had been done previously under the ABMG. In January 1994, a meeting was convened with board members of the ABGC and the genetic counseling program directors. A major objective of the meeting was to draft a set of practice-based competencies that an entry-level genetic counselor needs to demonstrate to effectively manage a genetic counseling session. These competencies served as the basis for the *Requirements for Graduate Programs in Genetic Counseling Seeking Accreditation by the American Board of Genetic Counseling*, adopted by the ABGC in January 1996. The 27 competencies are grouped into four domains (communication skills; critical-thinking skills; interpersonal, counseling, and psychosocial assessment skills; and professional ethics and values). These skills have become the cornerstone for curriculum design for programs seeking to achieve accreditation. The ABGC

moved away from the content-driven accreditation process developed under the ABMG with lists of courses and clinical contact hours, to an accreditation model that encourages the development of practice-based skills that integrate knowledge from several disciplines. With these practice-based competencies, the ABGC can hold the profession to a common set of expectations. The accreditation criteria for training programs are based on the program's ability to successfully develop these competencies in its genetic counseling graduates.

Additionally, ABGC established a recertification requirement for any diplomate certified in 1996 or later. Recertification was initiated to demonstrate a diplomate's commitment to maintaining knowledge in a rapidly evolving field. Through the recertification process, the ABGC strives to protect the public by ensuring the continuing education of genetic counselors. Recertification can be achieved in one of two ways: by either successfully passing another board exam or by collecting a specific number of continuing education units and professional activity credits over a specified period. Recertification has also proven significant for genetic counselors for licensing, professional advancement, hospital credentialing, and insurance reimbursement.

Since the formation of the ABGC, the number of Certified Genetic Counselors has grown from 495 to over 3,000. The number of accredited graduate training programs has increased from 18 to 33. By accrediting training programs, establishing competencies, and implementing recertification, the ABGC has been working hard to protect the public and promote the ongoing growth and development of practitioners in the genetic counseling profession.

Major Activities

The ABGC credentials genetic counselors and accredits genetic counseling training programs.

American Congress of Rehabilitation Medicine

Beth Garrison

Hartford Hospital Pain Treatment Center, Bristol, CT, USA

Major Areas or Mission Statement

The purpose of the American Congress of Rehabilitation Medicine (ACRM) is to advance service delivery and research for people who have disabling conditions. There are four major areas of focus for this research:

1. To meet the needs of people with disabilities
2. Educate providers for best practice delivery of care
3. Promote the health, independence, quality of life, and productivity of disabled people
4. To ensure that future research projects are publicly funded

The primary mission of the ACRM is to enhance the lives of disabled people via a multidisciplinary rehabilitation approach. As a leader in the physical medicine and rehabilitation field, their mission is to promote innovative research and new technologies and encourage evidence-

based practices in clinical settings as well as encourage information sharing.

Leadership role ACRM creates forums where all rehabilitation professionals, including clinicians, service managers, administrators, educators, and researchers, can innovate. We call upon the leaders in rehabilitation to identify current best practices and best providers at all levels of care, and share this information via educational meetings and the journal.

Archives of physical medicine and rehabilitation. As rehabilitation science and medicine continues to evolve, the goal is to keep the community connected by creating opportunities to exchange and share information with rehabilitation professionals, corporate providers, health-care payers, and industry regulators.

ACRM aims to provide multidisciplinary leadership and practice innovation to ensure that people living with chronic disease and disabilities have access to effective rehabilitation management throughout their lives. It serves as a forum for creating and discussing new treatment paradigms that define the composition of the rehabilitation team, the duration of care, and the venues required to achieve optimal functional outcomes for people with chronic disease and disabilities.

ACRM is dedicated to

- Serving as advocates for public policy and legislative issues that support individuals with disabilities and providers of rehabilitation services
- Helping develop innovative and cost-effective models of collaborative care and comprehensive rehabilitation management
- Leading research efforts that examine and identify the most effective clinical technology and treatment paradigms
- Initiating dialogue with payers and regulators to communicate the collaborative care models that produce positive rehabilitation outcomes

Landmark Contributions

The current title of American Congress of Rehabilitation Medicine became official in 1966. However, this congress was initially founded in 1923

as the American College of Radiology and Physiotherapy. It began as a professional association of physicians who used physical agents to diagnose and treat disability and illness. In 1925, with medicine already moving more toward specialization, the radiology and physical medicine focuses split. It became the American Congress of Physical Therapy. At that time, the congress' primary journal was the Archives of Physical Therapy, X-ray, Radium, which had been founded in 1920. In 1938, the name was changed to Archives of Physical Therapy, which more accurately reflected its focus.

Over the next 6 years, the congress' focus narrowed further toward physical medicine, and in 1944, the name was again changed to reflect this new direction. It was now the American Congress of Physical Medicine, and in 1945, the name of its journal became the Archives of Physical Medicine. This change in emphasis reflected the distinction that was growing between physical therapy and physical medicine. Physical medicine moved away from a purely clinical approach toward a scientific and diagnostic basis of the medical use of physical agents. It allowed a distinction between physicians and technicians of physical therapy in accord with the new stance of the American Medical Association (AMA).

By 1952, the field of rehabilitation had significantly expanded following WWII. To reflect the close relationship between physical medicine and rehabilitation, the name was changed to the American Congress of Physical Medicine and Rehabilitation. The following year, the journal name was changed to its current version, *Archives of Physical Medicine and Rehabilitation*.

In 1965, the congress formed the Professional Development Committee (PDC) which was pivotal in the management and direction of the ACRM for the next 30 years. This committee's accomplishments included a study of the objectives, constitution, and structure of the congress as well as the sponsorship of interdisciplinary forums and an expansion of the membership.

The following year, several physician members recognized the need for a forum in which professionals of other rehabilitation disciplines could share their professional, scientific, and technical talents. This led to an amendment to the

congress' constitution allowing membership privileges to be extended to persons "holding an earned doctoral degree and active in and contributing to the advancement of the field of rehabilitation medicine." This allowed the membership of psychologists, nurses, physical therapists, occupational therapists, speech pathologists, social workers, vocational counselors, and others. And in the same year, 1966, the name was officially changed to the American Congress of Rehabilitation Medicine.

Major Activities

ACRM membership is focused on interdisciplinary communication and collaboration within the rehabilitation professional community. This is accomplished by providing special interest and networking groups within the community, as well as providing publications and conferences that facilitate ongoing research, reference resources, and up-to-date developments in the field of physical rehabilitation medicine. Some of the resources available include the following:

- Fellows of ACRM
- Archives of Physical Medicine and Rehabilitation – a leading journal in rehabilitation
- Cognitive Rehabilitation Manual: Translating Evidence-Based Recommendations into Practice
- ACRM eNews
- Progress in Rehabilitation Research – an annual conference that brings together experts and participants from 20+ countries
- Midyear meeting for members and leaders within the community to collaborate and share information and refine guideline development
- Community calendar compiles a list of upcoming networking events and educational course offerings

American Medical Association

Fred R. Volkmar
 Child Study Center, Irving B. Harris Professor of
 Child Psychiatry, Pediatrics and Psychology, Yale
 Child Study Center, School of Medicine, Yale
 University, New Haven, CT, USA

Major Areas or Mission Statement

Membership is limited to physicians (with an M.D. or D.O. degree or international equivalent) who are in practice of residents in the United States and its possessions. Medical students can also enroll prior to completion of their training. About one quarter of US physicians are members of the organization.

The mission of the AMA is multifaceted and included improved public health, advocacy for physicians and their patients, and medical education. The AMA plays a major role in maintenance of medical coding that health-care providers use for reimbursement.

Landmark Contributions

The organization was founded in 1847 and incorporated 50 years later. It has a strong record of promotion of the scientific method in the practice of medicine and in the improvement of medical education. It also has had a major role in elaboration of principles of medical ethics and public health measures. It makes substantial contributions in support of medical students in financial need as well as grants for research and community projects. Over the years, many of its political positions have been controversial, for example,

including its initial opposition to Medicare. In recent years, it has focused on the disparities of health care and the special needs of some groups to medical services. Criticism of the organization has come from several sources including the noted economist Milton Friedman who argues that it has acted to limited competition.

Major Activities

The AMA publishes a series of journals in medicine. Of these, the *Journal of the American Medical Association* (JAMA) is the most prominent for the field of medicine in general, and the specialty journals of *Archives of General Psychiatry* and the *Archives of Pediatric and Adolescent Medicine* are most relevant to individuals with autism and other developmental disabilities.

American Psychiatric Association

Deborah Hales
 Division of Education, American Psychiatric
 Association, Arlington, VA, USA

Major Areas or Mission Statement

The mission of the American Psychiatric Association is to promote the highest quality care for

individuals with mental disorders (including mental retardation and substance-related disorders) and their families, promote psychiatric education and research, advance and represent the profession of psychiatry, and serve the professional needs of its membership.

Landmark Contributions

The American Psychiatric Association, founded in 1844, is the oldest national medical professional association in the United States and the world's largest psychiatric organization. Its member physicians work together to ensure humane care and effective treatment for all persons with mental disorders, including intellectual disability and substance-related disorders.

In 1948, APA formed a small task force to create a new standardized psychiatric classification system. This resulted in the 1952 publication of the first Diagnostic and Statistical Manual of Mental DisordersTM (DSM). The task force is currently developing DSM-5 to be published in May of 2013.

Major Activities

The APA publishes scientific journals:

The American Journal of Psychiatry publishes the latest advances in the diagnosis and treatment of mental illness. The findings presented in this journal explore the full spectrum of issues related to mental health diagnoses and treatment. Psychiatric Services, a journal of the American Psychiatric Association, is a journal for mental health professionals and others concerned with treatment and services for persons with mental illnesses and mental disabilities.

FOCUS: The Journal of Lifelong Learning in Psychiatry addresses clinical issues in psychiatry, featuring articles on current research including influential works selected by experts in the field. It also features an annual self-assessment exam and assists psychiatrists with recertification.

The APA's annual meeting brings together psychiatrists from all over the world to understand new research findings and acquire new knowledge and clinical issues in patient care.

American Psychological Association

Beau Reilly
Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, USA

Major Areas or Mission Statement

The primary mission of the APA is to “advance the creation, communication and application of psychological knowledge to benefit society and

improve people's lives" (APA.org). The APA states that within this mission contains the aspiration and vision to excel as a valuable, effective, and influential organization advancing psychology as a science (American Psychological Association 2002). This is accomplished by the organization's efforts to be:

- A uniting force for the discipline
- The major catalyst for the stimulation, growth, and dissemination of psychological science and practice
- The primary resource for all psychologists
- The premier innovator in the education, development, and training of psychological scientists, practitioners, and educators
- The leading advocate for psychological knowledge and practice informing policy makers and the public to improve public policy and daily living
- A principal leader and global partner promoting psychological knowledge and methods to facilitate the resolution of personal, societal, and global challenges in diverse, multicultural, and international contexts
- An effective champion of the application of psychology to promote human rights, health, well-being, and dignity
- Promoting research in psychology, the improvement of research methods and conditions, and the application of research findings
- Improving the qualifications and usefulness of psychologists by establishing high standards of ethics, conduct, education, and achievement
- Increasing and disseminating psychological knowledge through meetings, professional contacts, reports, papers, discussions, and publications

Landmark Contributions

The APA was founded in 1892 by G. Stanley Hall at Clark University in Worcester, Massachusetts, with approximately 26 individuals accepting membership at the time of its formation. Since the time of its inception, the APA has held prominent and historical members in the field of psychology as its president including William James (1894), James McKeen Cattell (1895), Edward Thorndike (1912), Carl Rogers (1947), Harry Harlow (1958), Abraham Maslow (1968), Albert Bandura (1974), and Phillip Zimbardo (2002).

The APA was responsible for the formation, review, and revision of the ethical codes of conduct and standards of practice. The code itself "is intended to provide guidance for psychologists and standards of professional conduct that can be applied by the APA and by other bodies that choose to adopt them" (APA 2002). The Ethics Code contains the following five general principles that are aspirational in nature and intended to be viewed as a guide to the highest possible standards of ethical practice:

- Continual pursuit of excellence
- Knowledge and application based on methods of science
- Outstanding service to its members and to society
- Social justice, diversity, and inclusion
- Ethical action in all that we do
- Beneficence and nonmaleficence
- Fidelity and responsibility
- Integrity
- Justice
- Respect for people's rights and dignity

The APA espouses the goal of seeking to advance psychology as a science, a profession, and as a means of promoting health, education, and human welfare by promoting and maintaining the following actions:

- Encouraging the development and application of psychology in the broadest manner
- The APA also formulated ten ethical standards of practices with specific guidelines in areas of psychology's application to a variety of domains. The standards set forth by the APA are enforceable by law and provide a guiding framework for

the competent and ethical practice of psychology. The ethical standard domains encompass:

- Resolving ethical issues
- Competence
- Human relations
- Privacy and confidentiality
- Advertising and other public statements
- Record keeping and fees
- Education and training
- Research and publication
- Assessment
- Therapy

Since 1955, the APA has provided the Model Act for State Licensure of Psychologists as a prototype to aid in the drafting of each state's specific legislation regarding the practice and licensing of psychologists in their respective states. The document is also meant to educate and inform legislators about the training and practice of psychology. It has undergone periodic revisions and updates since its inception (APA Committee on Legislation 1955). In 1984, the Council of Representatives directed the Board of Professional Affairs (BPA) to develop another revision of the existing 1967 Model Act for the council's consideration. The Committee on Professional Practice (COPP) prepared the revised document, and it was approved by the Council of Representatives in February 1987 (American Psychological Association 1987). In 2006, the 1987 Model Act was again revised by a task force funded by the APA Board of Directors and Council of Representatives at the recommendation of the Board of Professional Affairs and the Committee for the Advancement of Professional Practice. The primary reason for the changes in the existing Model Act was that it did not reflect the developments in professional practice that had occurred over the preceding 20 years across respective states. Specific developments included the option for prescriptive authority in some states, changes to the provision of industrial/organizational and consulting psychology services encouraging licensure for psychologist practicing in those arenas, and changes in the recommended sequence of education and training for

psychologists. The task force provided a comprehensive review of the 1987 document as well as relevant APA policies and other documents before creating a finalized draft of the new act. The newest revision was approved by council in February 2010 and includes commentary and guidelines for the following areas related to the practice of professional psychology (American Psychological Association 2010):

- Declaration of policy
- Definitions
- State psychology boards
- Requirements for licensure
- Interstate practice of psychology
- Temporary authorization to practice
- Limitations of practice, maintaining and expanding competence
- Inactive status
- Practice without a license
- Exemptions
- Grounds for suspensions or revocation of licenses
- Board hearing and investigations
- Privileged communication
- Severability
- Effective date

The Publication Manual of the American Psychological Association, currently in its sixth edition, has provided guidelines and recommendations for publication style intended for writers, editors, students, and educators in the social and behavioral sciences. It has grown considerably since its first publication in February of 1929 as a seven-page instructional report (American Psychological Association 2001). Over the subsequent 70 years, these suggestions and instructions were revised and expanded across six editions to its present form. The current manual provides guidance on all aspects of the scientific writing process, from the ethics of authorship to the word choice that best reduces bias in language. The manual additionally provides guidance on choosing the headings, tables, figures, and tone that will result in strong, simple, and elegant scientific communication. Every edition of the Publication Manual has been intended to aid authors in the

preparation of manuscripts with the primary goal of providing a standardized communication that will efficiently convey new ideas and research and to simplify the tasks of publishers, editors, authors, and readers. This has further allowed for the linkages of electronic files across publishers and manuscripts as new technological advancements in communication and distribution have emerged. This includes the maintenance and management of the abstract database, PsycINFO, which collects and distributes electronic information from approximately 2,500 journals dating from 1,800 to present (APA.org). Over a thousand journals in psychology, the behavioral sciences, nursing, and personal administration use the *Publication Manual* as their specified style guide (APA 2001).

Major Activities

The APA exists and operates as an executive office, a publishing operation, and an office that addresses administrative, business, information technology, and operational needs. It also contains five substantive directorates that address the needs of the field of psychology in its respective areas:

- The Education Directorate accredits doctoral psychology programs and addresses issues related to psychology education in secondary through graduate education.
- The Practice Directorate engages on behalf of practicing psychologists and health-care consumers.
- The Public Interest Directorate advances psychology as a means of addressing the fundamental problems of human welfare and promoting the equitable and just treatment of all segments of society.
- The Public and Member Communications Directorate is responsible for APA's outreach to its members and affiliates and to the general public.
- The Science Directorate provides support and voice for psychological scientists.

The American Psychologist is the APA's official journal and most highly circulated

peer-reviewed publication. The APA also publishes 57 other journals across a wide range of specialty and focus areas (APA.org). The APA also hosts the largest national convention and gathering of psychologists in the United States in a different host city each year. The convention provides seminars, conferences, presentations, and networking for all areas of psychology in its respective areas of research and practice.

Each year, the APA recognizes the work of psychologists with its "Distinguished Contributions Award." The awards are considered among the highest honors given and include recognition in the following categories:

- Distinguished Scientific Contributions to Psychology
- Distinguished Contributions to Psychology in the Public Interest
- Distinguished Scientific Applications of Psychology
- Distinguished Contributions to Education and Training in Psychology
- Distinguished Professional Contributions to Applied Research
- Distinguished Professional Contributions to Practice in the Public Sector
- Distinguished Contributions to the International Advancement of Psychology

The APA participates in a commitment to be an international partner with the global psychological community. Its office of International Affairs promotes exchange and collaboration with international communities including the United Nations. There are over 7,000 international members and affiliates of the APA (APA.org).

The APA has periodically provided commentary, guidelines, and recommendations to specific issues of practice and applications of psychology that impact current world events and ethical issues. Such issues and world topics have included task force reports on appropriate therapeutic responses to sexual orientation (APA Task Force on Appropriate Therapeutic Responses to Sexual Orientation 2009) as well as the use of military interrogation tactics (American Psychological Association 2007).

Division 33 (Mental Retardation and Developmental Disabilities) of the American Psychological Association was formed in 1973 as a unified division for psychologists committed to advancing psychology practice and research for individuals with mental retardation and developmental disabilities. In order to more accurately recognize the breadth of conditions that are now recognized to constitute developmental disabilities (e.g., autism, Asperger's disorder), the division changed its name from Mental Retardation to Mental Retardation and Developmental Disabilities in 1988 and to Intellectual and Developmental Disabilities in 2007 (APA.org). The division consists of five special interest groups: behavior modification and technology, dual diagnosis, early intervention, aging and adult development, and transitioning into adulthood. Members of Division 33 receive the newsletter "Psychology in Mental Retardation and Developmental Disabilities" three times per year and have access to the division's Listserv.

American Sign Language (ASL)

Vannesa T. Mueller

Speech-Language Pathology Program, University of Texas at El Paso College of Health Science, El Paso, TX, USA

Definition

American Sign Language (ASL) is the natural and national sign language of the deaf community in the United States and parts of Canada (Neidel et al. 2000). It is a natural language because it has developed out of a need for deaf individuals to communicate with each other, and it is a language that is in constant evolution. It is a national language because it is mutually intelligible and separate from the sign languages that are used in other countries such as British Sign Language (Great Britain), Mexican Sign Language (Mexico), and so forth. ASL is a separate language from spoken English (Lane et al. 1996), and it is distinct from manual codes of English such as Seeing Essential English (SEE I), Signing Exact English (SEE II), Linguistics of Verbal English (LOVE), or Conceptually Accurate Signed English (CASE). Unlike most other languages, ASL is typically learned from peers rather than from one's parents (Padden 1980). This may be due to the fact that most deaf children (about 90 %) are born to hearing parents (Mitchell and Karchmer 2004) rather than to deaf parents who could pass along the language to their children.

Historical Background

The American Sign Language that is used today is a combination of Parisian sign language that was

introduced in 1817 by Laurent Clerc, a teacher of the deaf from France, and the sign language that was used by the large community of deaf Americans at Martha's Vineyard (Baynton 1996). Despite attempts by some members of the normally hearing community to extinguish the language, the ASL that was used in the mid-1800s is still intelligible today to ASL users (Baynton 1996). William C. Stokoe Jr. first described ASL in his publication *Sign Language Structure* (Stokoe 1960). In it, he argued that indeed American Sign Language was a true and natural language and not merely gestures or pantomime. Stokoe followed this work with the first dictionary of American Sign Language.

Current Knowledge

Since the work of William Stokoe, much study has been focused on ASL specifically and sign languages in general. The field of linguistics has a greater understanding of language thanks to comparisons made between spoken languages and sign languages. Like spoken languages, sign language is comprised of syntax, semantics, morphology, and phonology (Sandler and Lillo-Martin 2006). We have much greater understanding of communication processes and language universals due to research on deaf adults who are victims of stroke or traumatic brain injury with resulting aphasia in sign language. The left hemisphere of the brain is largely responsible for language processing of sign language just as it is for spoken language (Corina 1998; Poizner et al. 1987). Both fluent and nonfluent aphasias in sign have been documented as well as paraphasias resulting from disordered phonology and morphology. See Hickok et al. (1998) and Woll and Sharma (2008) for a review of the literature.

Because users of spoken language use gestures to augment their messages, there is recent research on the role of gesture for those who use sign. Vermeerbergen and Demey (2007) show that gesture and sign can coexist and are often combined into one sign. Also, interestingly, the mouth and hands may trade tasks in fluent signers. For nonsigners, the mouth is responsible for transmitting verbal

information, while the hands are largely responsible for gesturing to augment the message. For signers, the mouth may be responsible for gesturing, while the hands convey linguistic information.

Much recent work has been focused on using technology to enhance the lives of the deaf population. There is great potential for converting sign to text and text to sign to create faster and more efficient exchanges between the deaf and hearing populations. The complexities of sign language, however, have made it difficult to automate a translation system to convert signed conversations to text. Two of the most commonly used input devices for capturing sign language gestures are glove-type devices and computer vision systems. Each system has advantages and drawbacks.

There have been a number of different glove-based devices used for input purposes (Hernandez-Rebollar et al. 2004). These devices typically contain several sensors per finger to measure the way the fingers move and the angle of the fingers as well as sensors to measure the pitch and roll of the hand. Proponents of these systems show that these input devices are able to more precisely detect handshapes than video-based systems (Fels and Hinton 1993; Hernandez-Rebollar et al. 2004). There are several disadvantages posed by data-glove devices (Wang et al. 2007). While extremely accurate, these devices were typically bulky and cumbersome as an individual wearing this device needed to be physically attached to the device that connects to a computer by means of cables. This need to tether the device to a computer limited how and where these devices could be used. The need to be physically connected is changing with advances in technology. Newer devices are employing technology such as electro-optical or magnetic sensors and accelerometers along with wireless capabilities to compensate for many of the early data-glove limitations (Dipietro et al. 2008). Even with advances in technology, these devices might interfere with natural movement and thus self-expression for individuals using them. Another factor that limits the use of these devices is the expense, which is typically more than for vision-based systems, although some of the costs have been reduced with new technology.

Gesture recognition based on computer vision systems utilizes a camera to detect hand movements and handshapes. Generally, these systems detect movement or the skin color of the hand to segment and extract features that can be used to model the hand. While the actual processes that each system employs vary, three basic types of methods are used to extract hand features:

1. Model-based or kinematic methods seek to model the angles created by the palm and joints of the hand.
2. View-based or appearance-based methods use multiple two-dimensional intensity images to model gestures as a sequence of views to overcome some of the shortcomings of kinematic models.
3. Low-level feature-based methods utilize low-level measurements of the hand region.

These methods do not rely on re-creating an exact model of the hand but rather attempt to capture just enough of the essential information needed to recognize gestures.

Opponents of video-based gesture recognition state that video-based systems are less able to recognize handshapes (Hernandez-Rebollar et al. 2004; Starner et al. 1997; Starner and Pentland 1998). Other challenges that video-based systems must overcome are specific lighting conditions needed to accurately capture the intended target as well as camera placement. Additionally, the subject being captured must remain in frame and the camera must not be obscured while recognition is underway. These limitations, particularly in earlier systems, made video-based systems difficult to use outside of the laboratory setting. Additionally processing the collected information to extract necessary features requires large amounts of computation that makes real-time processing difficult.

Current techniques in video-based gesture recognition address some of the earlier challenges including using multiple cameras, faster cameras, and better controlled environments and even having the users wear specially colored gloves (Murthy and Jadon 2009; Wang et al. 2007). In addition, the processing of the data collected has

improved by implementing processes such as hidden Markov models and the use of neural networks, but these tasks are still computationally expensive (Murthy and Jadon 2009).

Future Directions

The relationship between language and cognition is an area of continued interest and research. Much more can be learned regarding the processing of visual-spatial information from studies comparing native deaf signers, hearing signers, and hearing nonsigners. The area of normal sign language acquisition is in need of further exploration. With a better understanding of how sign language develops normally, we would be better able to identify disordered or delayed acquisition. The issue of bilingualism in sign language acquisition needs to be appraised more fully. Children who use ASL must become bilingual in their language of conversation (ASL) and their language of instruction which is most often English in many forms (written, signed, and spoken). Therefore, more studies should focus on bilingual acquisition. Few studies use a longitudinal design which would elucidate patterns in the development of sign language and help in the recognition of individual differences. Finally, as technology becomes smaller, less expensive, and more readily available, the applications for those with disabilities are limitless.

American Speech-Language-Hearing Association Functional Assessment of Communication Skills

Sarita Austin

Unlocking Language, London, UK

Synonyms

[ASHA FACS](#)

Description

The *American Speech-Language-Hearing Association Functional Assessment of Communication Skills* (ASHA FACS) measures and provides tools to monitor the functional communication of adults with certain speech, language, and cognitive impairments. Functional communication is the ability to effectively and independently communicate by sending or receiving messages, whether the individual uses speech, sign, pictures, or a speech-generating machine to convey the message.

Historical Background

This test was first published in 1995 to measure the ability of adults with left-hemisphere stroke and traumatic brain injury to execute their daily communication tasks. An addendum to this test

was published in 2004 that included normative data from individuals with right-hemisphere stroke, progressive neurological disease, and Alzheimer's disease and related dementias but not adults with communication deficits related to autism spectrum disorder (ASD). The extended validation of the test was also designed to support the use of this measure with multicultural populations in the United States and English-speaking populations internationally. The 2017 revised edition of the test includes the same test items and scoring procedures and an updated literature overview and presentation of validation studies in the manual.

Psychometric Data

Comparison data for the *American Speech-Language-Hearing Association Functional Assessment of Communication Skills* (ASHA FACS) test is based on the performance of individuals with aphasia, following left-hemisphere stroke, traumatic brain injury, dementia, and right-hemisphere stroke. While it may not be appropriate to use this data to evaluate the performance of adults with ASD, the test might be used informally to identify specific behaviors important to developing effective functional communication in adults with ASD. An individual's ability to perform the activities outlined on the ASHA FACS should allow the clinician to examine patterns of social communication and the comprehension and use of oral and written language.

Clinical Uses

The *American Speech-Language-Hearing Association Functional Assessment of Communication Skills* (ASHA FACS) is suggested for use with adults with speech, language, and cognitive difficulties following a stroke or traumatic brain injury or in the presence of progressive neurological disease, Alzheimer's disease, and related dementias. The assessment looks at the following areas: social communication, communication of needs,

daily planning, and reading, writing, and number concepts. Although not specifically designed or normed for the ASD population, the measure could be used informally to look at the daily communication abilities of adults and adolescents in this population.

Americans with Disabilities Act

Mark Sherry
Department of Sociology and Anthropology,
University of Toledo, Toledo, OH, USA

Definition

The *Americans with Disabilities Act* (ADA) is a landmark piece of Federal civil rights legislation which provides equal rights for people with disabilities throughout the United States. The ADA provided civil rights protections for people with disabilities in all programs funded by federal, state, and local governments. It prohibited discrimination on the basis of disability in the areas of employment, state and local government, public accommodations, transportation, telecommunications, and

commercial facilities. In 2008, the ADA was updated with the passage of the *ADA Amendments Act of 2008*, again expanding the coverage of civil rights protections for people with disabilities.

Areas Covered by the ADA

Employment

The ADA stipulates that employers are not allowed to inquire about whether a person has a disability, or the nature or severity of such disability, during the hiring or application process. The ADA also required certain employers (such as employment agencies, labor organizations, and joint labor-management committees) to provide “reasonable accommodations” to qualified individuals with a disability, unless it would impose extreme hardship on the employer. Reasonable accommodations include making existing facilities accessible to people with disabilities, changing work duties (including job restructuring, part-time or modified work schedules, reassignment to a vacant position) and also the provision of equipment, devices, or interpreters to enable a qualified person with a disability to perform the role. Determinations of extreme hardship take into account the size of the firm and the nature and cost of the reasonable accommodation, among other things.

Public Entities and Public Transportation

The ADA also prohibits public entities (such as state or local governments and federal transportation organizations) from engaging in discrimination against people with disabilities in their programs and services. This aspect of the law also requires public entities to provide paratransit and other special transportation services for individuals with disabilities, including making provisions for wheelchair users in public transport.

Public Accommodations and Services Operated by Private Entities

The ADA also prohibits discrimination against people with disabilities in terms of receiving goods, services, facilities, privileges, advantages,

or accommodations from “any place of public accommodation.” The term “public accommodation” is defined very broadly to include such places as hotels and motels; restaurants and bars; movie cinemas and theaters; convention centers and auditoriums; stores that sell food, clothing, or hardware; laundromats; travel centers; banks; pharmacies; parks and zoos; educational institutions (from nursery school to university); day care centers and senior centers; and gyms and health spas. However, religious institutions are not included in the ADA. Any new construction of such facilities must conform to the requirements of the ADA and be accessible to all users.

Telecommunications

Telecommunications carriers were required under the ADA to provide telecommunications relay services such as Teletype Writers and other telecommunications devices, particularly for people who are deaf or who have speech impairments.

Landmark ADA Cases

The ADA has been elaborated and refined under case law – in other words, courts have made rulings about the areas covered under the law over time. Some of the important cases which have affected the way the ADA is interpreted include *Bragdon v. Abbott*, 524 U.S. 624 (1998) which found that people with HIV were included in the ADA; *Sutton v. United Air Lines Inc.*, 119 S. Ct. 2139 (1999) which found that when deciding whether an individual is disabled, courts should consider measures that mitigate the individual’s impairment, such as eyeglasses and contact lenses; *Board of Trustees of University of Alabama v. Garrett*, 531 U.S. 356 (2001), which bars private money damages actions for state violations of employment discrimination against people with disabilities; *Barden v. The City of Sacramento* 292F.3d 1073, 1076 (9th Cir. 2002), which ruled that local governments must make sidewalks accessible when they made street improvements; and *Toyota Motor Manufacturing, Kentucky, Inc. v. Williams*, 534 U.S. 184 (2002), which narrowed the definition of disability by

ruling that an individual must prove they are prevented from performing major life activities in daily life (and not just workplace issues associated with their impairment) before they are considered “disabled” under the ADA.

Historical Background

The Rehabilitation Act of 1973

In the early 1970s, the disability rights movement, inspired by civil rights movement, had increasingly defined itself as a minority which was experiencing widespread discrimination. Its advocates played a key role in developing the legislative precursor to the ADA – the *Rehabilitation Act of 1973*. This Act was the first national piece of civil rights and antidiscrimination legislation for people with disabilities. Section 504 of the *Rehabilitation Act of 1973* which stated that “no qualified individual with a disability in the United States shall be excluded from, denied the benefits of, or be subjected to discrimination under” any program receiving federal funding – specifically the Federal Government, federal contractors, and recipients of federal financial assistance.

Section 504 of the *Rehabilitation Act of 1973* was historic for a number of reasons, including the fact that it recognized that people with disabilities were “a class” who experienced inferior treatment and discrimination because of a widespread pattern of discrimination and prejudice. From this viewpoint, people with disabilities could legitimately be considered a “minority group” – indeed, some activists called it “the biggest minority group in the country” because they estimated 20% of the entire population had a disability. Section 504 also involved treating people with different disabilities as members of the same minority group, replacing a long history of legislation aimed at specific groups of people with disabilities (such as veterans with disabilities, blind people, deaf people, and so on).

For 4 years, the disability rights movement engaged in continuous advocacy over the regulations which would be used to enforce Section 504. They argued that the regulations must require actions that would remove physical and

communicational barriers, as well as providing accommodations. Throughout the USA, disability activists engaged in “sit ins” – the longest of which occurred in San Francisco, lasting 28 days. The final regulations did meet the demands of these disability activists.

In the early 1980s, under the leadership of President Reagan, a task force was established to remove legislation which was excessively burdensome on business. Section 504 was identified as a potential burden for business, but the disability movement waged a 2-year campaign in defense of the legislation, and they were again successful. The regulations stayed in place.

Americans with Disabilities Act of 1990 (P.L. 101-336)

President George H.W. Bush signed into law the Americans with Disabilities Act of 1990 (P.L. 101-336). This was hailed as a major piece of civil rights legislation for people with disabilities. Whereas Section 504 of the Rehabilitation Act prohibited discrimination against individuals on the basis of disability in public entities, and services that received federal funding, the ADA extended the prohibition to private companies as well. Employers were prohibited from engaging in discrimination in every phase of employment: from recruitment and hiring to evaluation and promotion (Wehman 2001). Employers were again prohibited from discriminating against “otherwise qualified” individuals with a disability. The term “otherwise qualified” being a specific legal term. The employer who had an employee or job candidate who was “otherwise qualified” had to make “reasonable accommodations” in the workplace so that the individual could successfully perform his or her job. The scope of this piece of legislation was profound. According to Wehman (2001), this was a considerable challenge to 660,000 private businesses at the time that employed 8.6 million people. In fact, the law set up a timeline by which companies of various sizes had to insure their compliance with the ADA. By 1994, companies with 15 employees or more had to insure their compliance with ADA. Most major companies now employ at least one individual

whose job is to insure compliance with the law. The penalties for noncompliance are similar to those where a company is found guilty of discriminating against a person based upon gender or race. Government agencies are expected to comply with the law and face the same penalties as well.

Current Knowledge

Current knowledge about civil rights legislation for people with disabilities, and the ADA in particular, relies on an updated version of the Act, namely, the ADA Amendments Act of 2008. The central idea behind the ADA – that discrimination against people with disabilities was unlawful – is maintained in this Amendment, but other changes significantly alter the nature of disability rights in the USA.

Under the ADA Amendments Act of 2008, which came into effect on January 1, 2009, the US Congress reversed a series of court rulings which they viewed as limiting the rights of persons with disabilities. The Act specifically criticizes the findings of the judicial system in two of the cases discussed above (*Sutton v. United Air Lines* and *Toyota v. Williams*) for moving away from the initial intent of the ADA, which was to provide a broad-scale remedy to discrimination for people with disabilities.

The *ADA Amendments Act of 2008* also expanded the scope of those covered under the law: it applies not only to programs receiving local, state or federal funding, but also to all private employers with 15 or more employees, as well as businesses with fewer than 15 employees, if they are considered “places of public accommodation.” Such “places of public accommodation” include hotels, educational institutions, care providers, recreation facilities, transportation providers, and restaurants.

While the ADA was marked by conflict between the business community and disability advocates, the *ADA Amendments Act of 2008* broke such patterns of conflict, in some ways, because both business and disability advocates

agreed on a compromise which they unilaterally supported in testimonies to Congress. This was an interesting compromise because business representatives had criticized some disability activists for being “professional plaintiffs” who sought to earn an income by being overly litigious.

New Disability Definition

This Act clarified the intent of Congress to provide a broad definition of “major life activities” which might be affected by a person’s disability. Specifically, it stated that “major life activities include, but are not limited to, caring for oneself, performing manual tasks, seeing, hearing, eating, sleeping, walking, standing, lifting, bending, speaking, breathing, learning, reading, concentrating, thinking, communicating, and working.” The phrase “major life activity” also specifically included “the operation of a major bodily function, including but not limited to, functions of the immune system, normal cell growth, digestive, bowel, bladder, neurological, brain, respiratory, circulatory, endocrine, and reproductive functions.” As well, the Act overrode the findings in the *Sutton* case that “an impairment that substantially limits one major life activity need not limit other major life activities in order to be considered a disability.” Furthermore, the Act stated that defining disability should not be continuously reduced through a series of restrictive court decisions; instead, it states that the definition “shall be construed in favor of broad coverage of individuals under this Act, to the maximum extent permitted. . .”

The Act also stated that determining whether an impairment substantially limits a major life activity must be made without considering various mitigating measures such as medication, equipment, low-vision devices, prosthetics, hearing aids or cochlear implants, oxygen therapy equipment, or assistive technology. However, the Act states that the use of ordinary eyeglasses should be included in determining whether someone has an impairment that limits a major life activity. It also states that the ADA regulations

developed by the Equal Employment Opportunity Commission were inconsistent with congressional intent, relying on an excessively narrow definition of disability.

The Act does not apply retrospectively; it only applies after January 1, 2009.

Future Directions

Future cases will test the redefinition of “disability” through the court system. Congress has indicated that it wanted a more inclusive definition of disability, but how that actually plays out in specific cases and with specific disabilities (and degrees of disability) is yet to be determined. Additionally, upcoming cases will explore issues of compliance with the *Americans with Disabilities Act Amendments of 2008*.

Another issue which will be a major concern in the future is the degree to which the broad definition of disability within the *Americans with Disabilities Act Amendments of 2008* relates to other disability legislation such as the Individuals with Disabilities Education Act (IDEA) which potentially may result in confusion or inconsistent treatment of students in elementary and secondary schools.

Netherlands

Synonyms

[Alpha-amino acid](#)

Definition

Amino acids are molecules that contain an amine group, a carboxylic acid group, and a side chain built from carbon and hydrogen. Amino acids always include the elements carbon, nitrogen, oxygen, and hydrogen. An amino acid has the generic formula $H_2NCH(R)COOH$, where R is an organic substituent. The amino group is attached to the carbon atom immediately adjacent to the carboxylate group. Amino acids are the building blocks of proteins and important in various metabolic processes. Essential amino acids cannot be built by humans and need to be obtained through food intake.

[Amino acid disorders](#)

Definition

Aminoacidopathies, or amino acid disorders, are the result of an individual's inability to metabolize certain amino acids in proteins and/or detoxify the resultant by-products of that amino acid metabolism. The buildup of these amino acids and/or amino acid metabolism by-products in the blood can have severe medical implications, including autism spectrum disorders. Because amino acids are the key building blocks of many neurotransmitters, they are crucial to the proper regulation and development of cognitive, social, and emotional brain functions.

Serotonin, essential to the regulation of mood, is a monoamine neurotransmitter derived from tryptophan. Artificial depletion of tryptophan in autistic adults results in an increase in repetitive, anxious, and self-injurious behaviors. Plasma levels of tryptophan are significantly lower in autistic adolescents compared to age-matched unaffected individuals. In concordance with hypotheses of excitatory/inhibitory signaling imbalances in ASD patients, higher levels of glutamic acid and aspartic acid, both major excitatory neurotransmitter precursors, have been reported in ASD patients. Additionally, these patients show increased levels of taurine, an inhibitory neurotransmitter precursor, perhaps in a compensatory effort.

Of aminoacidopathies, phenylketonuria (PKU) probably bares the greatest symptomatic resemblance to ASD if left untreated in early childhood. PKU is caused by a mutation in the hepatic enzyme phenylalanine hydroxylase (PAH) gene, rendering the protein product nonfunctional. The PAH enzyme is responsible for the metabolism of the amino acid phenylalanine into tyrosine. Classic symptoms of PKU include mental retardation, behavioral or social problems, and seizures, all of which are also found in subsets of ASD patients.

Very recently there has been interest in homocysteine, a nonprotein amino acid not derived from diet. Vitamin B6, B9, and B12 deficiencies result in high levels of homocysteine, a neurotoxic state capable of inducing neuronal damage and cell loss through excitotoxicity and apoptosis. High levels of this amino acid have been found in autism patients.

Aminoacidopathies are often autosomal recessive and can be detected in urine samples for some amino acids and dried blood spot samples for others. Treatment usually involves dietary restrictions.

Amitriptyline

Jeffrey Glennon

Department of Cognitive Neuroscience, Radboud University Nijmegen Medical Centre, Nijmegen, The Netherlands

Synonyms

[Amitriptyline](#)

Indications

Depression, anxiety, enuresis nocturna, neuropathic pain, attention deficit/hyperactivity disorder (ADHD), obsessive-compulsive disorder (OCD).

Mechanisms of Action

Amitriptyline's key mechanism of action lies in the elevation of extracellular biogenic amine levels notably those of noradrenaline and serotonin (with noradrenaline being affected to a greater extent) by its blockade of cellular noradrenaline and serotonin reuptake transporters. In contrast, its metabolite nortriptyline has a more balanced action equally affecting both serotonin and noradrenaline levels. Amitriptyline exerts its function by blocking serotonin and noradrenaline reuptake. It is an antagonist at a number of receptors, notably serotonin 5-HT_{2A}, 5-HT_{2C}, 5-HT₃, 5-HT₆, and 5-HT₇, noradrenaline α_1 , histamine H₁, acetylcholine muscarinic receptors, and opiate σ_1 receptors.

Amitriptyline is absorbed from the gastrointestinal tract with highly varying peak plasma concentrations, occurring between 2 and 12 h after administration, where nearly all (95%) of the available amitriptyline is protein bound. Like all tricyclic antidepressants, amitriptyline is water soluble. The bioavailability of the active drug is between 30% and 60%, due to extensive first pass metabolism of the drug in the liver by the CYP2D6 enzyme.

The elimination half-life varies from 10 to 50 h, with an average of 15 h. Within 24 h, approximately 25–50% of a dose of amitriptyline is excreted in the urine as inactive metabolites; small amounts are excreted in the bile. Amitriptyline is demethylated in the liver to its primary active metabolite, nortriptyline by CYP450 1A2. Circulating therapeutic plasma levels typically lie between 110 and 250 ng/ml.

Specific Compounds and Properties

Amitriptyline is known by several brand names including Elavil, Laroxyl, Lentizol, and Sarotex. A generic version – Tryptizol – is also available. In terms of formulation, amitriptyline is available in solid tablet forms with intramuscular formulations available also. Typically, tablets are available in 50 and 100 mg doses.

Clinical Use (Including Side Effects)

Amitriptyline, whether administered orally or via intramuscular formulation, reaches peak plasma concentrations in both cases approximately 2–12 h after administration with onset commencing after 45 min. As already mentioned, the primary indication for amitriptyline use is as an antidepressant, but it also sometimes used for its sedative action. Therapeutic antidepressant effects are only seen after 2–3 weeks of therapy. In terms of child and adolescent usage, TCAs in general have been employed for more than 40 years and have been indicated not only in depression but also in attention deficit/hyperactivity disorder (ADHD), obsessive-compulsive disorder (OCD), separation anxiety, and nocturnal enuresis. In terms of its antidepressant action in children, this is mixed with its active metabolite nortriptyline showing more favorable effects. Other TCAs including desipramine and clomipramine have shown efficacy in ADHD and OCD, and as such, amitriptyline's usage in these disorders is off-label. In terms of the utility of TCAs in treating separation anxiety, this appears to be modest at best with further improvement seen when TCAs are combined with behavioral therapy.

Amitriptyline is metabolized primarily in the liver and is excreted both in feces and urine. In terms of its half-life, amitriptyline is typically associated with a half-life of between 31 and 36 h dependent on formulation and other factors. In reality, the half-life varies dependent on amitriptyline use and indication with administration for depression usually resorting to formulations with a half-life of 9–25 h, while the treatment of nocturnal enuresis (in children) is associated with dosages/formulations of between 18 and 96 h – where the active metabolite of amitriptyline, nortriptyline, plays a prominent role.

Typically, tricyclic antidepressants are not successful in treating prepubertal depression showing marginally better efficacy in adolescents for this indication. As such, the pharmacological treatment of choice for this indication remains selective serotonin reuptake inhibitors. In those child and adolescent subjects who do not respond to SSRIs, treatment of depression with tricyclic antidepressants (such as amitriptyline) has not been shown to be very productive in clinical studies. Due to their higher rate of metabolism, younger subjects often require higher mg/kg doses when compared to adults if amitriptyline use is warranted in depression. Special attention should be directed toward the higher rate of cardiotoxicity with amitriptyline in young subjects compared to adults, and this should be carefully monitored by both baseline and on-treatment ECG. Coprescribing with medications that prolong the QTc interval is not advised.

Dependent on the indication, dosing schedules of amitriptyline vary. For depression, it is advised to start with a dose of 25–100 mg/day. The dose can be increased up to 300 mg/day, although 100–150 mg per day is the recommended dosage. In elderly subjects, doses for the treatment of depression are typically half or one-third of the recommended adult dose, while its use for childhood depression is not indicated.

In the case of nocturnal enuresis, recommended doses typically range between 1 and 1.5 mg/kg of the body weight per day with doses to be taken in the afternoon. In children between 5 and 10 years old, these doses are usually in the range of

10–25 mg, while for adolescents between 11 and 16 years, these doses are typically 25–50 mg.

The use of amitriptyline against pain typically involves starting doses of 25 mg daily which can be increased up to 100 mg daily with 75 mg daily representing the active clinical dose in most patients. The benefits of amitriptyline treatment against pain are usually seen between 1 and 7 days after treatment onset.

The efficacy of treatment with amitriptyline can be improved and the onset of therapeutic effect hastened by measuring plasma levels to accurately titrate the therapeutic doses required. By monitoring drug compliance, amitriptyline dosing can be optimized. It is important that dosing has been stable for about 1 week prior to the assessment of blood samples with blood drawn between 10 and 14 h after the last intake advised for accurate monitoring. When monitoring plasma levels of amitriptyline, it is advisable to also measure its metabolite nortriptyline as nortriptyline is an active metabolite. Typically, therapeutic plasma levels of amitriptyline lie in the range of 50–200 µg/l, while those for nortriptyline usually are between 100 and 300 µg/l. With regard to drug safety, combined amitriptyline and nortriptyline concentrations of 500 µg/l are toxic.

Due to the high degree of plasma protein binding associated with amitriptyline, patients presenting with renal disorders often demonstrate altered plasma levels of amitriptyline and require careful dose monitoring.

Contraindications: Administration of amitriptyline during the recovery phase of cardiac infarction and glaucoma is highly contraindicated. Administration of amitriptyline in patients with epilepsy, organic brain damage, urine retention, prostate hyperplasia, pyloric stenosis, cardiovascular disease, hyperthyroidism, and diminished liver and kidney function is not advised but is not expressly contraindicated.

Interaction with Other Drugs: All selective serotonin reuptake inhibitors (SSRIs) such as fluvoxamine, with the exception of citalopram, may increase amitriptyline concentrations due to inhibition of the cytochrome CYP 2502D6. Other medications that can cause increased plasma levels are fluvoxamine, cimetidine, haloperidol, cimetidine,

and phenothiazines. Amitriptyline may decrease the effect of antihypertensive medication particularly guanethidine and clonidine, while coadministration with monoamine oxidase inhibitors may even induce a hypertensive crisis and demonstrate atropine-like toxic effects. Coadministration with phenothiazines may increase serum amitriptyline (or any other TCA for that matter) levels, while the effect of amitriptyline (or another TCA) is potentiated in the presence of thyroid preparations. Care should also be exercised requiring careful ECG monitoring when coadministering with thyroid preparations as these together can induce tachycardia and cardiac arrhythmia. For those taking oral contraceptives, these can inhibit the metabolism of TCAs including amitriptyline.

Amitriptyline is associated with strong additive anticholinergic effects when given in combination with anticholinergic agents. This additive action is also seen with CNS depressant ligands causing enhanced depressant effects or even severe cardiac effects such as heart block when combined with quinidine. Potentiation of sympathomimetic effects is also possible when amitriptyline is given in combination with sympathomimetics such as adrenaline.

Side Effects: Side effects associated with amitriptyline use include sedation, anhydrosis (decreased sweating), increased appetite, ataxia, anxiety, blurred vision, glaucoma, dry mouth, mydriasis (oversensitivity to light), headache, heartburn, decreased lacrimation, constipation, orthostatic hypotension, restlessness, sedation, sexual dysfunction (impotence, decreased libido), and urinary hesitancy and retention.

The management of some of the minor side effects is relatively straightforward, e.g., dry mouth can be managed by dry candy or mouth rinsing, mydriasis with sunglasses, orthostatic hypotension with slow positional changes, and decreased lacrimation with artificial tears.

Severe/life-threatening side effects associated with amitriptyline are rare events. However, these severe adverse events can include tachycardia, arrhythmias, extrapyramidal symptoms, glaucoma, hepatic failure, hyperthermia, suicidal ideations, mania, orthostatic hypotension, paralytic ileus, QTc prolongation, and seizures.

Precautions Associated with Amitriptyline

Use: Prior to starting treatment, it is advisable to take a medical history of cardiac problems, glaucoma, and seizures. Due to weight gain associated with amitriptyline use, it is important to measure weight, length, and BMI.

During treatment, it is important to address suicidal ideations, manic symptoms, and side unpleasant effects that might influence therapeutic compliance (e.g., sexual dysfunction). Addressing suicidal ideations is important since amitriptyline can increase suicidal ideations, and fatal overdose does not require a huge increase in dosage. It is therefore also important to be aware of potential hoarding of amitriptyline by patients which can be checked by careful monitoring of drug compliance in blood samples.

Overdosing: Individuals with diminished liver functions, plasma protein count/activity, and decreased total body water are at greater risk for overdose since metabolism occurs in the liver and usually nearly all ingested amitriptyline is bound to plasma proteins. Symptoms of overdose include apathy, coma, convulsions, cardiac arrhythmias, hypotension, and ultimately death.

Amphetamine

Lawrence David Scahill

Nursing and Child Psychiatry, Yale Child Study Center, Yale University School of Nursing, New Haven, CT, USA

Marcus Autism Center, Children's Healthcare of Atlanta, Atlanta, GA, USA

Department of Pediatrics, Emory University, Atlanta, GA, USA

Indications

ADHD

Mechanisms of Action

Amphetamines are stimulant medications that enhance the release and block the reuptake of dopamine in the brain. Taking at large doses, this mechanism of action can produce euphoria and increased energy. Because of these effects, amphetamines are subject to abuse. In doses used to treat attention deficit hyperactivity disorder, however, these stimulant effects are not usually present. The enhanced release of dopamine is presumed to be the source of improved attention and decreased activity.

Clinical Use (Including Side Effects)

Amphetamines are associated with many adverse effects that are relevant to children and adults with autism. For example, they can cause insomnia, decreased appetite, increased stereotypic behavior, and irritability. To date, the amphetamines have only been evaluated in small studies in children with autism with equivocal results. It appears

that the potency of the amphetamine compounds makes it difficult to find a dose that is helpful, but not associated with dose-limiting adverse effects.

Amygdala

Daniel P. Kennedy and Ralph Adolphs
Division of the Humanities and Social Sciences,
California Institute of Technology, Pasadena, CA,
USA

Synonyms

[Amygdaloid complex](#)

Structure

The amygdala is an almond-shaped structure located in the medial temporal lobe bilaterally, comprised of at least 13 nuclei in primates (Amaral et al. 1992; LeDoux 2007). It is a relatively small structure (considerably smaller than the hippocampus, which lies immediately anterior to), with approximately 12 million neurons in total occupying a volume of 4–5 cm³ in an adult human. It is well-documented that the individual subnuclei of the amygdala have distinct functions and distinct anatomical connectivity with other brain regions (both cortically and subcortically). However, given the difficulty in delineating the subnuclei reliably in living humans, the amygdala is often discussed as a single unitary structure

(as in the remainder of this chapter). There are probabilistic atlases for segmenting the amygdala into some of its subnuclei from structural magnetic resonance imaging (MRI), and this can be used to define likely locations that would fall within those nuclei, but not to precisely distinguish their boundaries. Detailed measures of the subnuclei, including stereological counts of the number of neurons, are however possible using postmortem brain tissue.

The largest subnucleus of the amygdala is the lateral nucleus, which receives most of the sensory inputs to the amygdala. In particular, the lateral nucleus receives projections from high-level visual cortex in the temporal lobe, as well as from many other polymodal association cortices. The basal nucleus of the amygdala, often lumped together with the lateral nucleus into the basolateral nucleus, contains neurons that project back to those regions from which the amygdala receives inputs. In primates, the basal nucleus also projects back to all of visual cortex, including early visual cortices (Freese and Amaral 2005). The medial nucleus likely serves an important role in other mammals as it is closely connected with the olfactory system. The central nucleus of the amygdala contains neurons that project to the hypothalamus and brainstem and regulate emotional responses. The internal circuitry of the amygdala is quite complex and is now being unraveled in great detail using optogenetic methods in mice.

Function

The amygdala's function is extremely diverse, reflected in the wide web of anatomical connections that it has with other brain regions. In addition to bidirectional connections with polymodal sensory cortex, it is connected with basal forebrain (modulating attention and flight versus freeze responses), hypothalamus, brainstem nuclei, periaqueductal gray (mediating various emotional behaviors), hippocampus (modulating memory consolidation), prefrontal cortex, and basal ganglia (modulating reward learning and

decision-making), among other regions. This diversity of connections permits the amygdala to modulate a large array of cognitive processes and aspects of behavior, including attention, memory, and reward learning. What ties all these varied aspects of cognition and behavior together is that the amygdala appears to serve a key role in processing those stimuli that have emotional or social value for an animal.

There are two main lines of research that document the amygdala's function in emotion and social behavior. Classic lesion studies in the 1930s suggested that the amygdala was needed for evaluating complex stimuli including social stimuli (Klüver and Bucy 1939), and subsequent lesion studies in monkeys (Emery et al. 2001; Machado and Bachevalier 2006) and humans (Adolphs et al. 1994) have verified this role. Lesions of the amygdala in monkeys produce a lack of cautionary behavior and a propensity to approach objects (including other animals and people) regardless of the context. For instance, whereas normal monkeys are very cautious in approaching novel stimuli or unfamiliar people, monkeys with amygdala lesions approach them readily without hesitation (Machado et al. 2009; Mason et al. 2006). Similarly, humans with amygdala lesions appear not to have a sense of personal space and show abnormally increased approach behaviors and ratings of trustworthiness and approachability of other people (Adolphs et al. 1998; Kennedy et al. 2009). This aspect of amygdala function has been investigated in humans most commonly by showing participants pictures of people and asking them to rate how much they would like to approach that person, or how much they would trust that person.

A second line of research originates primarily on work on rodents and has shown that the amygdala is necessary for learning about stimuli that predict harmful outcomes. The most studied protocol here is called Pavlovian fear conditioning, in which the animal must learn that a conditioned stimulus (such as a tone, or a particular color) predicts electric shock (Davis 2000; LeDoux 2000). Healthy animals, including humans, learn this association rapidly, whereas animals (including humans) with amygdala lesions do not. However, the amygdala is now known to

subserve a much broader role: it is also involved in appetitive learning, and it is also known to modulate declarative memory and instrumental behavior based on the value of stimuli (through projections to such structures as the hippocampus and the basal ganglia) (McGaugh 2004). Neurons recorded in the monkey amygdala show responses to stimuli that predict both aversive and appetitive outcomes, and these neurons appear to be intermingled throughout the basolateral amygdala (Paton et al. 2006). One current view of the amygdala's role in reward learning is thus that it is a primary locus for Pavlovian fear conditioning, but that it participates in other aspects of declarative and instrumental reward learning mostly through its interconnections with other brain structures.

Various attempts have been made to tie together the diverse roles of the amygdala in emotional and social processing. One view is that the amygdala, at least in humans, is somewhat specialized for aspects of social behavior or reward processing. Another view is that the amygdala carries out a much more basic and abstract computation, such as allocating processing resources to any events that are difficult to predict or novel. For instance, some human studies have argued for a fairly specialized role in recognizing social cues from facial expressions and perhaps especially from the eye region of faces (Adolphs et al. 2005). By contrast, other studies have shown broader attentional modulation based on any unpredictable stimulus, regardless of its social meaning (Herry et al. 2007; Whalen 2007). These current frameworks for understanding amygdala function are important for interpreting the amygdala's role in autism spectrum disorders, since they would point to different roles: in aspects of social dysfunction, or in sensory/attentional impairments, for instance.

Pathophysiology

Many have hypothesized that the amygdala plays a key role in the pathophysiology of autism (Bachevalier 1994; Baron-Cohen et al. 2000; Hetzler and Griffin 1981). Initially, however, there was little direct support for amygdala abnormality in autism, and much of the theory was

drawn from observing parallels between the autism phenotype and monkeys or rare humans with amygdala lesions. More recent studies have provided considerable additional evidence directly implicating the amygdala as a key region of neural dysfunction in autism, although the precise nature of the dysfunction, its etiology, and the extent of its contribution to the autism phenotype all remain intensely debated.

The first direct neural evidence to suggest that the amygdala might be abnormal in autism came from postmortem examination of brain tissue (M. Bauman and Kemper 1985), where increased cell-packing density and reduced cell size was noted. A recent follow-up study using modern quantitative methods did not replicate these findings (Schumann and Amaral 2006), likely due to methodological differences and differences in the study sample (e.g., exclusion of individuals with a history of seizures). Importantly, however, they did find significantly fewer neurons in the amygdala in the autism group.

Many studies have further examined the structure of the amygdala in autism using volumetric magnetic resonance imaging (MRI). Although this technique does not have anywhere near the spatial resolution of postmortem studies, the advantages are that it is a noninvasive technique, much larger sample sizes can be included, and one can obtain sufficient statistical power to examine clinical and behavioral correlates, as well as changes across the lifespan. Although volume is largely normal by adulthood, alterations in the early growth trajectory, growth from infancy on to late childhood, have been identified by cross-sectional and longitudinal studies, as well as cross-study comparisons (Mosconi et al. 2009; Schumann et al. 2004, 2009; Sparks et al. 2002). Specifically, the amygdala is enlarged early in development (before 2 years), but growth subsequently slows down and eventually converges with typical volumes by adolescence. In other words, the amygdala in autism undergoes an altered growth trajectory, wherein accelerated growth occurs early on but then gradually slows, so it is at the younger ages (and not adulthood) that the largest volumetric abnormalities can be observed. In addition, several studies have shown amygdala volumes in autism correlate with

various behavioral and clinical measures, such as social functioning, communicative development, and gaze patterns to faces (Mosconi et al. 2009; Munson et al. 2006; Nacewicz et al. 2006; Schumann et al. 2009). This altered growth trajectory, however, may not be specific to the amygdala alone, as total brain volume in autism also undergoes a similar pattern of abnormal development (Redcay and Courchesne 2005).

Studies that have examined the functioning of the amygdala in autism have also identified abnormalities. The primary methodology that is used to measure subcortical (and cortical) brain activity is functional MRI (fMRI) – a noninvasive technique that provides an indirect measure of neuronal activity based on changes in regional blood flow. fMRI provides reasonable spatial and temporal resolution, such that one can determine which stimuli or which cognitive process activates a particular 3–4 mm³ volume of brain tissue. However, subjects undergoing fMRI scanning are required to remain motionless for extended periods of time, and because of this, much of what is known about the functioning of the amygdala in autism comes from older children, adolescents, and adults and not young infants and toddlers (although this is now changing with several sites acquiring resting-state fMRI in sleeping infants). The first series of studies of amygdala functioning in autism found hypoactivation during performance of a variety of tasks, including making mental-state judgments from expressive eyes (Baron-Cohen et al. 1999), implicit processing of emotional faces (Critchley et al. 2000), and passive viewing of nonemotional faces (Pierce et al. 2001). However, these findings are by no means consistent across the literature, possibly due to differences in the tasks and stimuli used, differences in eye movements of participants, or differences in subject samples that reflect the heterogeneity of autism spectrum disorders.

Two notable studies have attempted to provide a more mechanistic account of amygdala abnormality in autism. One study found that amygdala activation in autism correlated positively with gaze to the eye region of faces (Dalton et al. 2005), consistent with other studies implicating the amygdala as involved in guiding eye movements towards eyes in faces (Adolphs et al. 2005;

Gamer and Buechel 2009). Given the well-documented behavioral abnormality that individuals with autism spend reduced time looking at the eyes in faces (Klin et al. 2002; Pelphrey et al. 2002), this may help to explain some of the above-described findings regarding amygdala hypoactivity. Another study (Kleinhans et al. 2009) found that the amygdala in autism exhibits abnormally reduced habituation overtime to repeatedly presented neutral faces, possibly pointing to a basic abnormality in habituation responses that have been found for amygdala neurons in other studies (Herry et al. 2007). The study in autism (Kleinhans et al. 2009) found that although the initial amygdala response was found to be slightly attenuated, the response remained elevated for longer than that observed in controls. The authors suggest that discrepancies across earlier studies might be explained by this altered time course of habituation.

Another promising approach to understanding amygdala dysfunction in autism is to examine the functional interaction between the amygdala and other brain regions. Individual brain regions do not function in isolation from one another, but rather comprise functional networks that exert reciprocal influences on other brain regions and other networks. So far, several studies have found that the amygdala exhibits abnormally reduced functional coupling with other brain regions, at least in the context of face processing tasks (Kleinhans et al. 2008; Rudie et al. 2012; Welchew et al. 2005). It is currently unclear, however, whether the amygdala is the primary source of this abnormality, or whether it simply reflects altered synaptic input (i.e., the abnormality is at the level of input rather than output). Many brain regions exhibit structural and functional abnormalities in autism, and these likely provide altered input to the amygdala.

It should be emphasized that although there is an abundance of evidence identifying the involvement of the amygdala in the social phenotype of autism, amygdala dysfunction is not thought to be the single cause of the autism phenotype. First, whether or not the amygdala contributes to other aspects of the phenotype (language delay, repetitive behaviors, restricted interests) is quite unclear. Second, given that many regions of the

brain are abnormal in autism, it seems likely that these brain regions also contribute to particular aspects of the autistic phenotype. Finally, complete lesions of the amygdala in both monkeys (Emery et al. 2001; Machado et al. 2009; Mason et al. 2006) and humans (Paul et al. 2010) do not result in autism and in several respects show symptoms that are the opposite of autism. There may be some more similarity in regard specifically to infant monkeys who had neonatal amygdala lesions (Bauman et al. 2008; Prather et al. 2001), further emphasizing that autism needs to be understood as emerging throughout a complex and prolonged developmental trajectory.

In sum, a convergence of evidence derived from a wide variety of experimental methods suggests that the amygdala is both structurally and functionally abnormal in autism. It is reasonable to assume that the amygdala is one component among a diverse set of brain regions that likely contribute to particular aspects of the autism phenotype. However, whether the amygdala plays a causal role in producing the core symptoms of autism or whether it is secondary in response to having autism has yet to be determined.

Functional analysis

Definition

A functional analysis is a controlled procedure for evaluating behavior function. The completion of an analog condition functional analysis requires the systematic manipulation of controlled environmental variables (Carr and Durand 1985; Iwata et al. 1982/1994). These manipulations are completed, in order, to precisely identify the maintaining variable, or variables, associated with a specific target behavior (e.g., aggression, stereotypy). By executing a series of analog conditions, investigators are able to track relevant reinforcement contingencies and formulate a functional hypothesis of maintaining variables (i.e., situations/factors associated with the problem behavior). These contingencies are considered representative of those occurring, in an integrated fashion, within the natural environment. An operational definition of a target behavior is constructed so that all investigators can reliably observe the occurrence of the response. This definition is then associated with a data collection procedure that is applied throughout all phases of the analysis. The conditions incorporated within the analysis must also be comprehensively defined for identical implementation through the assessment. Common conditions are

typically based on those outlined by Iwata et al. and include escape, attention, control, and alone. Additionally, a tangible condition is often incorporated within the analysis. Each condition is set up in a specific fashion based on certain environmental factors, and there are specific protocols for how the experimenter is to respond when the target behavior occurs. During the control condition, the patient is provided with continual access to high-preference materials, no demands, and high levels of attention. There are no environmental responses to the target behavior. During the alone condition, the patient is observed in a room without any preferred materials, demands, or attention. Again, there are no environmental responses to the target behavior. The demand condition requires continual presentation of specific demands to the patient. Upon an occurrence of the target behavior, the demands are removed for a defined interval, thereby offering negative reinforcement for the target behavior. The attention condition incorporates an introductory period of high-preference attention, which is then removed. The investigator, upon removing attention, remains close by but engaged in other activities. Following the occurrence of the target behavior, the patient is provided with a period of attention, thus offering positive reinforcement of the challenging behavior. The tangible condition allows the patient an introductory period of access to high-preference materials. These are then removed by the investigator but remain in view. The patient is provided defined periods of access to the materials, contingent on the occurrence of the target behavior, thereby establishing a positive reinforcement contingency for the target behavior. The conditions are randomly implemented and replicated until a reliable trend emerges. Defined, individual-specific, modifications to analog conditions are incorporated based upon the needs of the patient and are subject to equal requirements for reliable and replicated implementation.

Analysis of Verbal Behavior (AVB)

Trina D. Spencer
 Rightpath Research and Innovation Center,
 University of South Florida, Tampa, FL, USA
 Institute for Human Development, Northern
 Arizona University, Flagstaff, AZ, USA

Definition

In his book *Verbal Behavior* (1957), B. F. Skinner defined verbal behavior as “behavior reinforced through the mediation of other persons” (p. 2). Following this definition, filling a glass with water results in a filled glass and is not verbal behavior, whereas saying, “Can you fill my glass?” depends on the behavior of another person to *mediate* the consequence of the request to fill the glass. Because verbal behavior does not act on the environment directly but rather through the behavior of others, it requires a separate analysis. Nonetheless, Skinner asserts that the same behavioral principles of reinforcement, punishment, and discrimination can account for verbal behavior (i.e., communication) as they do for any other behavior.

Historical Background

In 1934, Alfred North Whitehead challenged Skinner to use behavioral principles to account for language. Despite Whitehead’s cynicism, Skinner began his book *Verbal Behavior* (1957), which took him over 20 years to complete. Shortly

after its publication, Noam Chomsky, who had his own account of language, published a critical review of *Verbal Behavior* and behaviorism. Chomsky's criticisms were not surprising because Skinner's analysis differed significantly from the popular linguist perspective in two important ways. First, the analysis of verbal behavior involved considering units of language based on their function instead of their structure. Second, the analysis of verbal behavior proposed that language is learned behavior, which is shaped and maintained by environmental variables.

Despite the attention this debate attracted, Skinner never responded to Chomsky's review supposing that Chomsky misunderstood the philosophical foundations of behaviorism. In the years since, many have interpreted Skinner's silence as a loss. Although proponents of the analysis of verbal behavior dispute this assumption, it may have impeded widespread adoption of Skinner's analysis of verbal behavior. The linguistic theories that bind language development to physiological processes have flourished despite criticisms about their limited value for language intervention and treatment. However, a theory of language that leads to useful and effective treatments is important, especially for individuals with autism.

In the late 1980s, Ivar Lovaas developed and evaluated a discrete trial training (DTT) model for teaching children with autism. Although based on operant conditioning and behavioral principles, DTT does not align perfectly with Skinner's analysis of verbal behavior. There are two primary differences between a DTT approach to teaching children with autism and an approach based on Skinner's *Verbal Behavior*. First, although some instruction occurs in structured settings, verbal behavior interventions emphasize the importance of natural environment teaching (NET) and make use of naturally occurring learning opportunities. In the Lovaas approach, children are primarily taught in highly structured learning environments. Second, the analysis of verbal behavior suggests that, in addition to antecedents and consequences, motivating variables are crucial in the development of language. Understanding the motivating conditions for the basic verbal behaviors influences the type of antecedents and consequences

used (or captured) for training. In contrast, the Lovaas approach de-emphasizes the motivating variables of the different verbal behaviors and conducts training using edible or tangible consequences and social praise almost exclusively. Although generalization is a key component of both approaches, interventions based on the analysis of verbal behavior are more likely to begin teaching under more naturally occurring motivating conditions, whereas in the Lovaas approach, generalization trials are typically conducted after behaviors are established in highly structured, analog environments.

Rationale or Underlying Theory

There are two kinds of language analyses: formal and functional. A formal analysis considers what verbal behavior looks like or its form (also called topography). The linguistic perspective is formal because words and grammatical structures are the units of analysis. In contrast, Skinner analyzed verbal behavior in terms of functional units. This use of functional does not mean useful but rather causal. In other words, the cause of the behavior is more important to its understanding than what the behavior looks like. A functional unit takes into account the verbal behavior of interest (e.g., mand, tact, intraverbal) and its related antecedents, consequences, and motivating variables. According to this analysis, basic verbal behaviors are defined by the conditions and variables that control them (i.e., their cause).

Defined specifically by the functional variables controlling their use, Skinner proposed a number of elementary verbal behaviors: mand, tact, echoic, and intraverbal. *Mands* are under the functional control of motivating variables (e.g., deprivation, aversive stimulation) and specific reinforcement. Mands are like demands, commands, or requests because they include information about what is wanted or needed. For example, a speaker has not had a drink in a long time (deprivation) says, "Can I have a drink?" (mand) and receives a glass of water (specific reinforcement) from a listener. A *tact* is controlled by nonverbal antecedent stimuli and generalized reinforcement such as attention

or approval. If a glass of water sat on the counter (nonverbal antecedent stimulus) and upon seeing it the speaker said, “water” and was given approval (generalized reinforcement) from a listener, the response “water” is a tact. *Echoic* behaviors are those that are controlled by verbal antecedent stimuli with a matching response form and generalized reinforcement. For example, a person (speaker 1) models the verbal response “water” (verbal antecedent stimulus), and a second person (speaker 2) repeats “water” (echoic) and receives praise (generalized reinforcement) from speaker 1 for making the response sound like the model. *Intraverbals* are also controlled by verbal antecedent stimuli and generalized reinforcement. However, intraverbals are not similar in form to their verbal antecedent stimuli like echoic behaviors. If instead of modeling the verbal behavior “water” in the echoic example, the first speaker had asked, “What is your favorite drink?” (verbal antecedent stimulus) and the second speaker said, “water” and received approval (generalized reinforcement), the response “water” would be an intraverbal.

Goals and Objectives

Skinner’s *Verbal Behavior* is a theoretical framework with direct implications for teaching verbal behavior to individuals with language deficits (e.g., children with autism). A functional analysis of language leads to informative language assessment, a recognition of naturally occurring motivating variables, an emphasis on mands as principal communication skills, and intraverbal instruction to promote language development beyond the basics. Parents and professionals can draw from the analysis of verbal behavior to make decisions regarding instructional approaches such as augmentative communication, discrete trial training vs. natural environment teaching, and inclusion. For example, from a verbal behavior perspective, a more complete language repertoire can be acquired through a combination of discrete trial training (DTT) and natural environment teaching (NET) procedures. For children with autism, inclusion in regular education may be more effective once children master the basic verbal behaviors

(i.e., mand, tact, and intraverbal) necessary to benefit from an integrated learning environment.

Treatment Participants

The analysis of verbal behavior applies to all humans; however, interventions based on this analysis have been designed primarily for children and adults with autism and other developmental disabilities. Skinner’s analysis is not restricted to individuals with language deficits.

Treatment Procedures

Interventions based on the analysis of verbal behavior include a variety of procedures. There is not one standardized model of verbal behavior treatment. However, there are many teaching procedures that are common among them such as the manipulation of motivating variables, prompting, shaping, fading, and transfer of stimulus control. Verbal behavior interventions are likely to balance opportunities for instruction in highly structured, teacher-directed (e.g., discrete trial training) arrangements with opportunities for incidental, child-directed instruction (e.g., natural environment teaching) to capture natural motivating conditions. See ► [“Verbal Behavior Interventions”](#).

Efficacy Information

Based primarily on its conceptual logic, Skinner’s analysis has been applied in the treatment of children with autism for several decades. The Analysis of Verbal Behavior (TAVB), a journal dedicated to publishing verbal behavior research, was first published in 1982. As a result, there is a growing body of literature supporting the main premises of Skinner’s analysis of verbal behavior and demonstrating efficacy of teaching procedures based on the analysis (Sautter and LeBlanc 2006). Much of this literature involves individuals with autism as participants. However, there are no studies that document the outcome of the long-

term application of treatment based on the analysis of verbal behavior and only one study comparing verbal behavior and linguistic approaches to instruction (Carr and Firth 2005).

Outcome Measurement

There are two widely used measurement tools based on Skinner's analysis of verbal behavior. The *Assessment of Basic Language and Learning Skills* (ABLLS; Partington and Sundberg 1998; Partington 2010) is a criterion referenced assessment, curriculum guide, and tracking system for children covering basic learner skills (e.g., imitation, requests, intraverbals), academic skills (e.g., reading, math), self-help skills, and motor skills. A companion manual *Teaching Language to Children with Autism or Other Developmental Disabilities* (Sundberg and Partington 1998) was published at the same time as the ABLLS. In 2010, Partington published the ABLLS-Revised, which is a common tool used for school age children with autism and other developmental disabilities. In 2008, Sundberg published his own assessment tool that integrates developmental milestones with key verbal behaviors. The *Verbal Behavior-Milestone Assessment and Placement Program* (VB-MAPP) includes a stronger focus on placement and individualized education program (IEP) development and subsections for milestones, barriers, and transitions.

Qualifications of Treatment Providers

Although the analysis of verbal behavior can be used to derive treatment procedures, Skinner did not specify a set of tactics to teach verbal behavior. Likewise, there are also no provider qualifications. That being said, Skinner's book *Verbal Behavior* is incredibly complex. Its technical content is appropriate for individuals with an invested interest. Summaries of Skinner's main tenets can be found in more beginner-friendly formats (see References).

Professionals who apply the analysis of verbal behavior in the treatment of individuals with autism need to have advanced training in applied behavior analysis, verbal behavior, and extensive

supervised experience implementing verbal behavior interventions. Preferably, verbal behavior providers have been credentialed by the Behavior Analysis Certification Board (BACB) or have completed the equivalent training. In general, verbal behavior interventions require that providers have more skill and training than discrete trial training (DTT) procedures do.

Definition

An anecdotal observation is a factual account of an incident. The precise sequence of events is documented using descriptive language in order to describe exactly what occurs during a given situation. The setting and context are also carefully described. Subjective statements and judgments should be avoided during anecdotal observations. Therefore, a written anecdotal observation should provide the reader with a clear picture of the event.

In autism, anecdotal observations are often helpful in learning more about a child's behavior. Parents may be asked to make anecdotal observations of their child in order to keep a detailed record of their behavior, monitor their response to particular events, track progress during intervention, or provide information about their behavior following a change. Such information can be valuable for a service provider during assessment or when developing and/or maintaining a therapy program. School staff and treatment providers may decide to use their own anecdotal observations as evidence for the need to implement or modify a treatment program or intervention strategy. For example, an anecdotal observation during the school day may reveal deterioration in a child's behavior whenever there is a school assembly. Tracking these events and responses via direct observations can be useful in determining a pattern of behavioral challenges. They may provide the support necessary to put strategies in place in order to prepare the child for assembly days. Parents and service providers can analyze anecdotal observations to determine patterns such as these and better serve children in need.

Although anecdotal observations can provide a deeper understanding of behavior in one particular individual, caution should be used when applying any conclusions drawn from the observation to other individuals. Because anecdotal observations are individualized to a specific event and person, generalizations to other individuals may not be valid and can at times lead to faulty conclusions, even for those in a similar situation or who have the same diagnosis. Furthermore, anecdotal observations should not replace controlled studies when making judgments about causal relationships because

Short Description or Definition

Prader-Willi syndrome (PWS) and Angelman syndrome (AS) are two distinct neurodevelopmental disorders caused by mutations in the same region of the genome, involving chromosome 15q11.2-15q13.3.

Categorization

Genetic syndromes, Neurodevelopmental disorders.

Epidemiology

The prevalence of PWS is approximately 1 in 10,000 individuals (Dykens et al. [2011](#)). The prevalence of AS is 1 in 12,000–20,000 individuals (Williams et al. [2010](#)).

Natural History, Prognostic Factors, Outcomes

Infants with PWS have severe hypotonia and difficulties with feeding. The latter evolves into hyperphagia (excessive eating) and morbid obesity. Obesity-related problems, such as non-insulin-dependent diabetes mellitus, are the most serious health issues. Weight control becomes critical for maximizing health outcomes. Children with PWS experience multiple developmental delays in cognition, language, motor skills, and physical growth. Short stature and hypogonadism are common, the latter affecting pubertal development and resulting in infertility.

Children with AS also experience multiple developmental delays in cognition, language, motor skills (gait ataxia), and physical growth (microcephaly). Seizures, which typically occur during infancy and the toddler years, can be of varied types. In contrast to PWS, individuals with AS have normal pubertal development and fertility. Aside from possible seizures, they typically have good health and normal life spans. They require lifelong supervision.

Clinical Expression and Pathophysiology

A key concept to understanding these syndromes is genomic imprinting. Typically, a child inherits two copies of each gene, one transmitted from the father and one from the mother. In many instances, these pairs of genes work in concert to achieve full function. In the region denoted chromosome 15q11.2–15q13.3, there are a number of genes which are only active (translated to proteins), depending on whether they are inherited from the father or mother. This phenomenon, in which a gene or genes is silent on either maternally or paternally transmitted chromosome, is termed imprinting.

In PWS, 70% of cases are due to a deletion involving the segment 15q11.2–15q13.3 of the paternal chromosome. Because many of the genes in this region are imprinted (or silent) on the maternal chromosome, this results in the loss of all gene products. Another 25% of cases are due to maternal uniparental disomy, a condition in which both copies of the chromosome are inherited from the mother. Five percent of cases are due to chromosomal breakpoints which disrupt genes within the region or mutations which affect the proper imprinting of this interval. While it has not been definitively determined which gene(s) in the interval cause PWS, recently deficiency of paternally expressed small nucleolar RNAs (snoRNAs) has been considered the leading suspects. These RNAs regulate the expression of another gene which is involved in serotonin neurotransmission, the serotonin 2C receptor (Dykens et al. 2011). AS is due to deficiency of the maternally expressed UBE3A gene. This gene shows paternal imprinting, meaning it is silent on the paternal chromosome. Sixty-five to seventy-five percent of cases are due to deletions of the maternal chromosome, 5–11% are due to mutations in the UBE3A gene, 3–7% are due to paternal uniparental disomy (both copies of the chromosome are inherited from the father), and 3% of cases are due to imprinting mutations (Williams et al. 2010).

The chromosome 15q11.2–15q13.3 region has also been implicated in autism spectrum disorders (ASDs). A high proportion of patients

with duplications at this locus meets diagnostic criteria for ASD (Abrahams and Geschwind 2008). Conversely, in some clinical ASD cohorts, up to 1% of patients show maternal duplications of this interval (Sanders et al. 2011). It is among the most common chromosomal rearrangements seen in ASD. There are quite a few overlapping clinical features between PWS and ASD, and it has been suggested that the conventional autism diagnostic tests (ADOS and ADI-R) may not be sufficient to discriminate between PWS and ASDs (Dykens et al. 2011). Greater than 40% of patients with AS have ASD, although the converse is rare (proportion of patients with ASD who have AS).

Evaluation and Differential Diagnosis

PWS is a common cause of hypotonia at birth and may be identified early by genetic testing. If this is not identified early, clinical diagnosis is suspected based on the combination of short stature, behavioral issues, and hyperphagia, typically after age 6. The diagnosis can be confirmed in the vast majority of cases via DNA testing. It is characterized by a wide range of symptoms, many of which are behavioral or endocrine in nature. One of the most common symptoms associated with the disorder is an insatiable appetite that often leads to morbid obesity. This is due to dysfunction of the hypothalamus, the region of the brain which regulates feelings of satiety and hunger (Butler 2011). Patients with PWS have high levels of ghrelin, a compound that is found in the lining of the stomach and stimulates hunger, but whether this finding is a cause or consequence of primary problems in PWS is not known. The typical psychiatric difficulties faced by people with PWS include anxiety and compulsive behavior, including skin picking. Smaller subsets of patients are affected by symptoms such as depression, hallucination, and paranoia. In almost all cases, people with PWS have below average intelligence, with the median IQ being in the 50–70 range (Dykens et al. 2011).

The diagnosis of AS is usually suspected by early developmental delay and behavioral

manifestations and can be confirmed by DNA testing. It is characterized by severe cognitive and neurological impairment. While the manifestation and severity of symptoms varies greatly, there are a few which are the most common, appearing in almost 100% of cases. Patients always experience severe developmental delay as well as movement and balance issues. Consistently, patients are afflicted with speech impairment. Some are nonverbal, while others have very limited vocabulary. One characteristic trait of individuals with AS is their apparently happy demeanor, frequent laughter, and hand flapping. Slightly less common traits are diminished head size and the onset of seizures before the age of 3. Clinical diagnosis of AS can be complicated. Usually, a successful diagnosis involves motor and speech delays, as well as the characteristic motor mannerisms and demeanor (Cassidy et al. 2000). If AS is suspected, an EEG (electroencephalogram) may be performed to rule out gelastic seizure, a rare type of seizure which is accompanied by a burst of energy (Williams 2005).

Treatment

There is no cure for PWS; however, there are treatments to lessen symptoms. These include starting physical therapy early to help with muscle tone. Children should be placed in a structured school environment with close teacher supervision. Occupational and speech therapy should be provided if needed. Strict supervision of diet is required to address hyperphagia and prevent morbid obesity and its attendant health problems. Clinical trials of growth hormone replacement therapy have shown cognitive as well as physical benefits (Cassidy and Schwartz 2009). The latter includes increasing height, lean body mass, and mobility and decreasing fat. Adults with PWS most often require supervised living situations and work environments.

As with PWS, there is no cure for AS, but medications are used to treat the various symptoms. This includes anticonvulsants to combat the seizures, melatonin to encourage regular sleep

patterns, and laxatives for regular bowel movements. Beginning physical and occupational therapy early is also important to promote muscle development and decrease joint stiffness. Given the typically severe speech impairment, speech therapy should emphasize nonverbal methods of communication, such as picture cards (Dagli and Williams 2011). AS is not degenerative; in fact, many symptoms improve with age, such as seizures, sleep issues, and continence. Life expectancy is average, and while people with AS may never be fully independent, adults can learn basic daily living skills.

Anger Rumination in Children with Autism Spectrum Disorder

Karim Ibrahim, Rebecca Jordan, Sonia Rowley and Denis G. Sukhodolsky
Child Study Center, Yale School of Medicine,
Yale University, New Haven, CT, USA

Definition

Anger rumination is a cognitive-emotional process referring to the tendency to dwell on frustrating experiences and recall past anger experiences (Sukhodolsky et al. 2001). More generally, rumination represents a maladaptive form of emotion processing that entails remaining focused on the stressor through repetitive and passive dwelling upon distress, past mistakes, regrets, and shortcomings (Nolen-Hoeksema 1991; Nolen-Hoeksema et al. 2008). Further, rumination may hinder the use of cognitive control strategies such as reappraisal and problem-solving (Nolen-Hoeksema 1991; Nolen-Hoeksema et al. 2008), most likely due to prolongation of negative affect. While rumination is shown to be associated with internalizing disorders such as anxiety and depression (Connor-Smith et al. 2000; Nolen-Hoeksema et al. 2008), rumination may also be a factor in other forms of maladaptive behaviors such as

disruptive behaviors including irritability/anger and aggression (Aldao et al. 2016; McLaughlin et al. 2014; Nolen-Hoeksema and Watkins 2011).

Historical Background

The Anger Rumination Scale (ARS) was developed by Sukhodolsky et al. (2001) to assess cognitive processes that unfold during and continue after the emotion of anger has been generated. The ARS is a widely used and well-established self-report measure of the construct of anger-focused rumination. The ARS includes 19 items assessing the cognitive processes related to feelings of anger, the tendency to think about anger-provoking situations, and tendency to recall past anger episodes. The ARS has four subscales that measure anger afterthoughts, thoughts of revenge, angry memories, and understanding of causes. The subscales anger afterthoughts and thoughts of revenge correspond to thinking about a recent episode or recalling and getting angry about a distant episode, while the subscales angry memories and understanding of causes correspond to thinking about causes of an anger episode in order to achieve a meaningful understanding of the episode. Higher scores on the ARS indicate a greater level of anger rumination. Further, the ARS has demonstrated high internal reliability for use with children with ASD and children with disruptive behaviors (alphas >0.8) (Ibrahim et al. 2019; Patel et al. 2017; Smith et al. 2016), as well as adequate test-retest reliability ($r = 0.77$).

Current Knowledge

Anger Rumination and Associations with Co-occurring Disorders in ASD

Over 50% of children with autism spectrum disorder (ASD) have co-occurring disruptive behavior disorders and/or internalizing disorders (Aldao et al. 2016; McLaughlin et al. 2014; Nolen-Hoeksema and Watkins 2011) that cause distress and impairment in various domains of functioning. Additionally, children and adults with ASD exhibit elevated levels of anger rumination

relative to typically developing controls, which is also associated with co-occurring internalizing and/or externalizing symptoms. For instance, several studies have consistently reported an association between anger rumination and disruptive behaviors (Ibrahim et al. 2019; Patel et al. 2017; Pugliese et al. 2015). Consistent with studies of non-ASD populations indicating greater levels of anger rumination in youths with DBD (Harmon et al. 2017; Smith et al. 2016), recent work also suggests that children with ASD may show levels of anger rumination that are greater relative to typically developing controls, but similar to children with disruptive behavior disorders without ASD (Ibrahim et al. 2019). Further, there is evidence to suggest that children with ASD and co-occurring disruptive behavior may show greater levels of anger rumination relative to children with ASD without disruptive behavior (Ibrahim et al. 2019). The developmental trajectory of rumination broadly may also predict increased disruptive behavior in later adolescence in youths with ASD (Bos et al. 2018). Anger rumination has also been linked to anxiety symptoms and disruptive behaviors in young adults in the general population, in which symptoms of social anxiety may predict greater levels of anger rumination and, thereby, increased levels of disruptive behavior (Pugliese et al. 2015). Lastly, associations between anger rumination and depressive symptoms have also been reported in youths with ASD (Patel et al. 2017). Thus, similar patterns of elevated anger rumination across ASD and disruptive behavior disorders lend support to the notion that rumination more broadly may be a transdiagnostic factor (Aldao et al. 2016). Additionally, similar patterns of elevated anger rumination in ASD and non-ASD populations with disruptive behavior could also suggest shared aberrations in the mechanisms subserving cognitive control.

Anger Rumination and the Relationship with Core ASD Symptoms

Recent work implicates rumination in general with core ASD symptoms such as restricted and repetitive behaviors (RRBs) including an insistence on sameness, inflexible adherence to routines, rigidity of thought, and perseveration (Gotham et al. 2014; Keenan et al. 2017). For

instance, studies have suggested a relationship between a greater tendency to engage in anger rumination and the severity of core ASD symptoms, particularly RRBs (Ibrahim et al. 2019; Patel et al. 2017; Pugliese et al. 2015). A recent study compared samples of children with and without ASD and disruptive behavior and reported an interaction between ASD diagnosis and RRBs in predicting anger rumination; that is, the presence of an ASD diagnosis and greater severity of RRBs was related to higher levels of anger rumination (Ibrahim et al. 2019). Further, levels of anger rumination were found to be positively correlated with the severity of RRBs when modeled dimensionally across the total sample of youths with ASD (Ibrahim et al. 2019). Another study showed that levels of perseveration were found to augment the relationship between anger-focused rumination and disruptive behaviors (Pugliese et al. 2015). It should also be noted that other forms of rumination including depressive rumination have also been shown to be associated with perseveration in young adults (Keenan et al. 2017) as well as adults with ASD (Gotham et al. 2014). Lastly, Patel et al. (2017) demonstrated that anger rumination in children was positively correlated with overall core ASD symptoms, including social communication and interaction and RRBs symptoms. Thus, it is also possible that specific types of RRBs, such as insistence on sameness and perseveration, could differentially contribute to levels of anger rumination in ASD (Gotham et al. 2014; Pugliese et al. 2015). However, future studies are needed that include measures of perseveration on circumscribed interests to understand whether anger rumination is a manifestation of a perseverative type of repetitive behavior or a distinct trait.

Rumination and Emotion Dysregulation in ASD

It has also been hypothesized that the association between rumination more broadly and RRBs may contribute to overall emotion dysregulation in ASD, which could suggest common underlying deficits in cognitive control neural circuitry (Mazefsky et al. 2013). It is possible that anger rumination may be part of the constellation of core ASD symptoms, particularly RRBs including

rigidity of thinking, insistence on sameness, and perseveration. It is also important to emphasize that other forms of ruminative thoughts, including depressive rumination, have been shown to be associated with RRBs in individuals with ASD (Jahromi et al. 2012; Mazefsky et al. 2013, 2014; Rieffe et al. 2011). Thus, greater difficulty disengaging from perseverative thoughts could predispose children with ASD to engage in rumination (Mazefsky et al. 2012). Additionally, in children and adults with ASD, impairments in emotional reactivity and cognitive control in combination with RRBs may hinder the use of adaptive, voluntary emotion regulation strategies, such as reappraisal and problem-solving (Ibrahim et al. 2019).

Models of emotion dysregulation in ASD propose that amplified emotional reactivity paired with poor cognitive control may characterize emotion regulation impairments in ASD, predisposing children with ASD to an increased risk for developing co-occurring psychiatric disorders (Mazefsky et al. 2013). The tendency of individuals with ASD to engage in high levels of rumination or maladaptive cognitive control patterns compared to non-ASD populations could suggest broader deficits in the underlying mechanism of emotion regulation in ASD (Mazefsky et al. 2013). For instance, given that emotion regulation impairments are common in ASD, reliance on involuntary maladaptive strategies such as suppression and rumination may hinder the use of adaptive regulation processes such as cognitive reappraisal or problem-solving (Mazefsky et al. 2012). Thus, the tendency to engage in anger rumination, or ruminative thoughts in general, could also be related to broader deficits in emotion regulation in ASD. Further, the overlap between anger rumination, emotion dysregulation, and RRBs could predispose children with ASD to a heightened risk for disruptive behaviors.

Future Directions

Given the relationships between anger rumination, or rumination more broadly, co-occurring disorders, and repetitive behaviors in ASD such as perseveration, this area of inquiry has the potential to advance understanding of the underlying mechanisms of

emotion dysregulation and the overlap of anger rumination with core ASD symptoms. Future research on rumination in ASD could also pave the way for new, more effective treatments that target perseverative thoughts, as well as for improved diagnostic approaches that can more accurately distinguish between rumination, perseveration, and other associated symptoms such as anxiety and disruptive behavior. Therefore, a better understanding of the mechanisms underlying anger rumination in ASD could contribute to the development of novel treatments for decreasing disruptive behaviors and improving emotion regulation strategies (Jahromi et al. 2012; Mazefsky et al. 2013, 2014; Rieffe et al. 2011). For example, future studies could examine whether perseverative tendencies of individuals with ASD are associated with anxiety, disruptive behavior, and depressive symptoms or whether perseveration could be harnessed in interventions to increase recall of positive autobiographic memories. Given the high prevalence of comorbid psychiatric disorders among individuals with ASD and DBDs (Lecavalier et al. 2019; Leyfer et al. 2006; Simonoff et al. 2008; van Steensel et al. 2013), more studies are needed with sufficiently large samples to compare anger rumination in children with ASD and co-occurring DBDs to children with DBDs without ASD in order to better understand the overlap between core ASD symptoms and disruptive behaviors in predicting anger rumination. Additionally, given the increased prevalence of trauma in children with ASD (Haruvi-Lamdan et al. 2017; Kerns et al. 2015) and the role that rumination may play in strengthening the association between trauma symptoms and anger (Spinhoven et al. 2015), future studies are needed that examine the effects of co-occurring trauma, such as maltreatment or bullying, in ASD and its relationship to anger rumination and core ASD symptoms. Finally, it will be important to understand the impact of sex differences on anger rumination in children with ASD.

Institute of Mental Health, NIH, Porter
Neuroscience Research Center, Bethesda, MD,
USA

Definition

Animal models are useful for testing hypotheses about biological mechanisms underlying the causes and symptoms of human psychiatric disorders and for systematically evaluating the effects of potential treatments. Though animal models cannot fully encapsulate all aspects of autism, mouse behaviors with strong conceptual analogies to the diagnostic symptoms of autism have been identified. Assays currently in use include tests for social approach, reciprocal social interactions, social communication, repetitive behaviors, and restricted interests. These tasks have been employed to test hypotheses about the genetic and environmental causes of autism. Detection of rodent models with endophenotypes highly relevant to the symptoms of autism is likely to enable the discovery of effective therapeutic interventions.

Historical Background

Animal models of human neuropsychiatric disorders are in widespread use for biomedical research. Many rodent behavioral tasks relevant to the symptoms of these disorders have been developed, and psychopharmacological treatments for many major mental illnesses and neurological diseases have been evaluated in translational rodent models (Covington et al. 2010; Crawley 2007b; Higgins and Jacobsen 2003; Moore 2010). Developing animal models relevant to the symptoms of autism spectrum disorders (ASDs) presents a unique challenge to the biomedical research community. Autism is a complex neurodevelopmental disorder marked by considerable clinical heterogeneity. The diagnostic criteria for autism are behaviorally defined by three criteria: (1) aberrant reciprocal social interactions, (2) impaired communication, and (3) stereotyped repetitive behaviors with restricted narrow interests (American Psychiatric Association 1994; Dawson et al. 2002; Kanner 1943; Piven et al. 1997; Volkmar and Pauls 2003). It is important to note that none of the currently available models fully recapitulate all aspects of ASDs. However, fundamental symptoms of autism can be approximated in animal models in order to test hypotheses about mechanisms underlying the etiology and causes of the disorder and to evaluate potential pharmacological, behavioral, and other treatments that may alleviate symptoms associated with ASDs.

Current Knowledge

Strategies for Designing Rodent Models of Autism

Twin and family studies indicate an extraordinarily high degree of heritability for ASDs. Concordance between monozygotic twins approaches 90% for ASDs as compared with 10% or less in dizygotic twins and approximately 0.6–1.0% occurrence in the general population (Abrahams and Geschwind 2008). Several approaches have been used to generate genetic mouse models of autism and to evaluate the contributions of

specific genes to the symptoms of ASDs. Genes implicated in autism include those coding for proteins involved in synapse development, neuronal signaling, neurotransmission, neuron survival, RNA transcription, and DNA methylation. Targeted mutations in genes homologous or orthologous to human candidate genes for autism have generated a large number of genetic mouse models (Bozdagi et al. 2010; Cheh et al. 2006; DeLorey et al. 2008; Etherton et al. 2009; Hines et al. 2008; Kwon et al. 2006; Nakatani et al. 2009; Peca et al. 2011; Shu et al. 2005; Winslow and Insel 2002). *Mus musculus*, the house mouse species used in molecular genetics research, is a social species that engages in high levels of reciprocal social interaction and social communication, communal nesting, sexual and parenting behaviors, territorial scent marking, and aggressive behaviors (Arakawa et al. 2008; Bolivar et al. 2007; Miczek et al. 2001; Moretti et al. 2005; Scattoni et al. 2009; Terranova and Laviola 2001; Winslow and Insel 2002). Table 1 summarizes autism-relevant behavioral phenotypes in some prominent genetic mouse models of autism.

A second approach, also using mouse models, addresses single-gene neurodevelopmental disorders and those resulting from chromosomal deletions and duplications (copy number variations, CNVs), in which a high number of affected individuals display autism-like symptoms. Lines of mice have been generated with targeted gene mutations relevant to disorders such as Angelman syndrome, fragile X syndrome, Rett syndrome, Timothy syndrome, and tuberous sclerosis (Ehninger et al. 2010; Moretti et al. 2005; Spencer et al. 2011). A mutant mouse line with a duplicated chromosome orthologous to human chromosome 15q11–13 has also recently been generated (Nakatani et al. 2009). Table 2 summarizes autism-relevant behavioral phenotypes in selected mouse models of single-gene neurodevelopmental disorders and disorders resulting from rare CNVs.

A third approach is to generate defects in rats or mice that model reports of autism following exposure to teratogenic drugs, environmental toxins, or prenatal insults. For example, increased risk for autism has been associated with prenatal exposure to the anticonvulsant drug valproic acid,

the antiemetic drug thalidomide, and prenatal viral infections. Models that address hypotheses regarding environmental causes of autism include offspring of pregnant rats and mice treated with valproic acid or immunostimulant compounds that simulate viral infection (Ehninger et al. 2010; reviewed in Dufour-Rainfray et al. 2011, and Patterson 2009). Table 3 summarizes findings of autism-relevant behavioral phenotypes in mouse and rat models used to test hypotheses about environmental factors implicated in autism.

A final approach consists of utilizing naturally occurring variation among genetically diverse inbred mouse strains to identify behavioral phenotypes with strong face validity to ASD symptoms (Bolivar et al. 2007; Brodtkin et al. 2004; Moy et al. 2004, 2007, 2008b; Panksepp et al. 2007). Investigation of inbred strains expressing traits relevant to autism is referred to as a “forward genetics” approach and is analogous to human linkage studies aimed at discovering genes linked to autism (Abrahams and Geschwind 2008). Table 4 lists examples of autism-relevant behavioral phenotypes that have been detected in different inbred strains of mice.

Because no consistent biological markers for autism have been identified, the diagnosis of autism is currently based on standardized evaluation instruments such as ADOS and ADI, which score well-defined behavioral symptoms. In consultation with autism clinical experts, behavioral neuroscientists are refining standard behavioral assays available in the literature and developing new behavioral assays which maximize face validity to the diagnostic symptoms of autism. Reviewed here are the tests that have been most useful, along with the essential control measures, for modeling the diagnostic and associated symptoms of autism in animals.

Rodent Behavioral Tasks Relevant to the Diagnostic Symptoms of Autism

Sociability

The first DSM-IV criterion for autism is qualitative and quantitative impairments in social interactions (APA 1994; Lord et al. 2000; Piven et al. 1997; Volkmar and Pauls 2003). These

Animal Models, Table 1 Autism-relevant behavioral phenotypes in selected mouse models with targeted mutations in genes homologous or orthologous to human candidate genes for autism

impairments have been characterized as a lack of interest in others, unusual and inappropriate social approach behaviors, lack of social reciprocity, and failure to develop peer relationships appropriate to developmental ages (Kanner 1943; Lord et al. 2000; Piven et al. 1997; Volkmar and Pauls 2003). Assays used to detect social interaction abnormalities in rodent models of autism include measures of social approach, the partition test, reciprocal social interactions, the visible burrow test, social recognition, and social preference tests.

The automated three-chambered social approach apparatus, developed by Nadler, Moy, Crawley, and colleagues (2004), compares time that a subject mouse spends with a novel mouse versus time that a subject mouse spends with a novel object (Brodkin et al. 2004; DeLorey et al. 2008; Hines et al. 2008; McFarlane et al. 2008; Moy et al. 2004, 2009; Nadler et al. 2004; Nakatani et al. 2009; Ryan et al. 2010). Detailed procedures for conducting this task are available (Yang et al. 2011b). The subject mouse is first

Animal Models, Table 2 Selected examples of mouse models of genetic syndromes in which a portion of patients display autistic behaviors

Genetic syndrome	Genetic syndrome characteristics	Mouse model	Autism-relevant behavioral phenotypes
Fragile X syndrome	Lack of fragile X mental retardation protein (FMRP) production; associated with cognitive impairments, hyperactivity, social anxiety, attention problems, executive function impairments, and autistic-like behavior in affected males	Mice with a targeted mutation in the murine <i>Fmr1</i> gene	Low sociability ^{a, b}
			Reduced reciprocal social interactions ^a
			Reduced social interest during a partition test ^a
			High levels of self-grooming ^a
			Increased motor stereotypies and repetitive marble burying ^a
			Resistance to change in a selective attention task ^a
Rett syndrome	Loss of function mutations in the X-linked gene methyl-CpG-binding protein 2 (<i>MECP2</i>); characterized by loss of acquired motor, social, and language skills beginning at 6–18 months of age and nonsyndromic mental retardation	Mice with a heterozygous mutation in the murine <i>Mecp2</i> gene	Social avoidance ^c
			Reduced reciprocal social interactions ^c
Chromosome 15q duplication syndrome	Duplication at chromosome 15q11–13; implicated in ASDs in several association studies	Duplication in the genomic region on the mouse chromosome 7 homologous to the human genomic region 15q11–13	Low sociability ^d
			Ultrasonic vocalizations increased in pups and reduced in adults ^d
			Impaired reversal learning ^d

placed in the empty center chamber to habituate to the novelty of the environment (shown in Fig. 1). After the 10-min habituation session, the subject mouse is returned to the center chamber, while the targets are placed in the left and right side chambers. A novel object is placed in one side chamber. The novel object is usually an inverted wire pencil cup that elicits considerable exploration and sniffing by the subject mouse. A novel mouse is placed in the other side chamber, inside in a wire cup that permits visual, olfactory, auditory, and

some tactile contact while preventing aggressive or sexual interactions. The number of seconds spent in each chamber, and the number of entries between chambers, is automatically recorded by the software detection of photocell beam breaks in the partitions between the compartments. Sociability in this task is defined as the subject mouse spending more time in the side chamber containing the novel mouse than in the side chamber containing the novel object. Equal or less time spent with the novel object as compared to the

novel mouse is interpreted as the absence of sociability in this task. Mice investigate novel conspecifics by sniffing. Thus, to determine whether time spent in the chamber containing the novel mouse reflects true social interactions versus nonsocial exploration of the chamber, a human observer scores, from videotapes of the test session, the amount of time the subject mouse spends sniffing the wire cup containing the novel mouse. Investigating the novel object instead of the novel mouse may be analogous to the tendency of autistic individuals to engage in nonsocial activities such as playing with one toy for an extended period of time or to spend more time visually examining geometric patterns as compared to social images (Frith 2003; Pierce et al. 2011).

The partition test (Spencer et al. 2011) can be used to evaluate social interest as well as basic social recognition. A subject mouse is placed in one side of a standard cage divided in half by a perforated partition made of clear plastic or wire and a partner mouse in the opposite side. The subject mouse can see, hear, and smell the partner mouse, but cannot engage in physical interactions with the partner. Approaches to and time spent at the partition by the subject mouse represent the amount of interest in the social partner. Social

preference and social memory can be evaluated through sequential presentation of different social partners.

To more fully assess the complexity and variability of social behaviors in mice, more fine-grained analyses of reciprocal social interactions can be conducted in freely moving dyads of mice. Behaviors exhibited by two unfamiliar age-matched rats or mice can be detected with automated video-tracking equipment or scored by a human observer. A variety of parameters can be scored depending on the age and sex of the animals, including nose-to-nose sniffing, nose-to-anogenital sniffing, body sniffing, following, pushing past each other with physical contact, crawling over and under each other, chasing, mounting, and wrestling (Bolivar et al. 2007; McFarlane et al. 2008; Terranova and Laviola 2001). Nonsocial behaviors such as self-grooming, repetitive digging in the bedding, and arena exploration are simultaneously scored. Subject animals can be tested at different ages and over repeated test sessions to evaluate trajectories of complex social behaviors across different neurodevelopmental stages. A juvenile play apparatus for scoring reciprocal social interactions in 21-day-old mice is shown in Fig. 2.

The visible burrow system can be used to evaluate social interactions among adult mice in a context that provides many features of rodents' natural habitats, including multiple burrows connected via tunnels to a larger open area (Arakawa et al. 2007). Behaviors displayed in the visible burrow system can be videotaped and scored later by a human observer. Social behaviors such as huddling, chasing, following, and mounting can be scored along with nonsocial behaviors such as self-grooming and fleeing from another animal (Arakawa et al. 2007; Pobbe et al. 2010). Food and water can be provided in the visible burrow system to allow observation of social behaviors at different times of day over several consecutive days or weeks.

Manual scoring of rodent social behaviors requires highly trained human observers, is often time-consuming and is subject to observer bias. A growing number of video-tracking software systems are becoming available to automate

Animal Models, Table 4 Examples of genetically homogeneous inbred mouse strains that display behavioral phenotypes relevant to the diagnostic symptoms of autism

scoring of social behaviors in rodents. Several different software programs have been shown to be reasonably accurate for quantifying social approach behaviors in mouse models of autism using the three-chambered apparatus (e.g., Nadler et al. 2004; Page et al. 2009). Use of more sophisticated software packages to automatically score reciprocal social interactions between pairs of animals is also on the rise (Ahern et al. 2009; Searce-Levie et al. 2008). However, the degree to which these programs accurately track multiple animals has not yet been systematically evaluated,

or has their ability to capture the subtleties inherent to the rodent social behavior repertoire. If their accuracy can be verified, use of automated software programs with standardized quantification methods may allow higher-throughput scoring of rodent social behaviors while improving the chances of reproducibility of results across labs.

Social preference tests can be used to evaluate components of social affiliation, social recognition, and social memory in rodents. In these tests, the subject animal is offered a choice between partners, and time spent with each partner is

measured. In partner preference tests, two stimulus animals with different characteristics (e.g., different strain, familiar versus unfamiliar) are presented simultaneously. The time spent with and number of approaches to each stimulus animal can then be recorded and used to calculate a preference score (Williams et al. 1992). Partner preference tests are often conducted in a Y-maze apparatus where freely moving subject mice spend time with tethered target mice in three cages connected by tunnels (e.g., Lim et al. 2004; Winslow et al. 1993). The three-chambered social approach apparatus (shown in Fig. 1) has been used to investigate preference for social

Animal Models, Fig. 1 Three-chambered social approach apparatus used to evaluate sociability and preference for social novelty in mice. (Photograph contributed by Dr. Mu Yang, Laboratory of Behavioral Neuroscience, NIMH)

novelty in mice (DeLorey et al. 2008; Moy et al. 2004, 2009). Preference for social novelty is defined as the subject mouse spending more time in a chamber or in physical contact with a novel mouse in one side chamber than with a familiar mouse in the other side chamber. Mice usually habituate quickly to the presence of a novel conspecific and will move on to approach and investigate another novel conspecific when it is presented. During social approach testing as described above, the subject mouse becomes habituated to the novel mouse. The subject mouse can then be provided access to a second unfamiliar novel mouse, and time spent with the first versus second novel mouse can then be recorded. Partners can also be presented sequentially, with time delays between presentations, to evaluate social recognition memory (Winslow and Insel 2002). A lack of normal preference for a novel social partner or deficits in social recognition may be analogous to the tendency of autistic individuals to avoid unfamiliar individuals or to indiscriminately approach strangers (American Psychiatric Association 1994).

Communication

The second DSM-IV criterion for autism, qualitative impairments in communication (American Psychiatric Association 1994; Frith 2003; Lord et al. 2000), is perhaps the most challenging to model in rodents. The nature of mouse communication is not yet well understood, although considerable interest has recently focused on

Animal Models, Fig. 2 (a) Noldus PhenoTyper 3000 apparatus for scoring reciprocal social interactions between pairs of age-matched unfamiliar mice. (b) Two

juvenile C57BL/6/J mice engaged in nose-to-nose sniffing. (Photographs contributed by Dr. Mu Yang, Laboratory of Behavioral Neuroscience, NIMH)

ultrasonic vocalizations (Lahvis et al. 2011; Scattoni et al. 2009). Olfaction is the primary sense used by rats and mice for individual recognition and is likely of central importance in rodent communication (Brennan and Kendrick 2006). Information between members of the same species is conveyed using chemical signals commonly termed pheromones. In addition to pheromonal communication, rats and mice emit ultrasonic vocalizations in different social contexts throughout the lifespan (Lahvis et al. 2011; Scattoni et al. 2009). Several behavioral tasks involving the evaluation of responses to olfactory and auditory cues can be used to assay possible communication deficits in rodents.

Tasks designed to assay olfactory communication in rodents include social transmission of food preference, olfactory habituation/dishabituation to social odors, and scent marking. The social transmission of food preference test is a three-stage process. First, a “demonstrator” animal is allowed to eat a novel-flavored food. After consuming the novel food, the demonstrator interacts with an “observer” animal. During this time, the observer animal acquires familiarity with the novel flavor, presumably by sniffing the face, breath, and whiskers of the demonstrator animal. In the final phase, the observer is given a choice between the flavor of the food eaten by the demonstrator and some other novel flavor. The observer animal will express a preference for the now-familiar food as indicated by eating more of it. Normal performance on this task is thought to depend on the observer animal detecting olfactory cues on the breath of the demonstrator, which requires social interactions, particularly nose-to-nose sniffing (Galef and Wigmore 1983; Wrenn 2004).

The olfactory habituation/dishabituation task (shown in Fig. 3) measures the ability to detect and discriminate between different odors. When mice are presented with a cotton swab containing a novel odor, they will investigate it by sniffing. Upon repeated presentations of the same odor, a progressive decrease in sniffing (olfactory habituation), will be seen. Reinstatement of high sniffing levels (dishabituation) will be seen when a novel odor stimulus is subsequently introduced (Ryan

Animal Models, Fig. 3 Olfactory habituation/dishabituation test, showing a mouse sniffing a cotton swab saturated with odors from an unfamiliar mouse. (Photograph contributed by the authors)

et al. 2010; Yang and Crawley 2009). Fresh urine or swipes from the bottom of a soiled cage of unfamiliar mice can be used as social odors. The shapes of the habituation and dishabituation curves reflect the ability to discriminate between same and different odors. The peaks of the curves reflect the level of interest in each odor stimulus. Social odors elicit considerably higher levels of sniffing as compared to nonsocial odors, such as almond and banana extracts (Yang and Crawley 2009).

Olfactory cues influence a variety of social behaviors in rodents, such as kin and individual recognition, bond formation, mate attraction and selection, and communication of danger (Arakawa et al. 2008; Brennan and Kendrick 2006; Hurst 1990). Scent-marking tasks are widely used in mice (Arakawa et al. 2008; Wöhr et al. 2011). Mice deposit urinary steroidal pheromones that serve as territorial scent marks and are distinct among genetically diverse individuals (Brennan and Kendrick 2006). High levels of interest in urinary scents from other mice are indicated by the tendency of a subject mouse to explore the anogenital area of a novel mouse, investigate urinary scent marks in a cage, and sniff a cotton swab soaked in urine from another mouse. When a male mouse encounters a scent mark deposited by another male in its territory, it tends to countermark in response. Countermarking is gradually reduced when a male mouse is repeatedly exposed to scent marks from the same mouse and is increased again when the subject mouse encounters scent marks from a

novel, genetically different mouse (Arakawa et al. 2008). Thus, countermarking behavior might be useful for studying the ability to discriminate between different individuals based on olfactory cues. Male mice also deposit scent marks when exposed to urine from a female mouse (Wöhr et al. 2011). Female urine-elicited scent marking is thought to play a role in mate attraction and could serve as a measure of social motivation (Hurst 1990; Wöhr et al. 2011). The importance of olfactory cues across many social contexts suggests that rodent models of autism displaying olfactory communication deficits might be useful for understanding aspects of impaired social communication in autism.

Emission of ultrasonic vocalizations (USVs) in social situations is a consistent and robust phenomenon in rodents. These USVs can be detected using sensitive ultrasonic microphones and recorded using specialized software. Quantitative and qualitative analysis of USVs emitted by mice have been used to examine possible autism-relevant communication deficits in both inbred strains and various genetic mutant mouse lines.

When separated from the nest, mouse pups emit calls that parents use to locate and retrieve the pup (Nakatani et al. 2009; Scattoni et al. 2008; Shu et al. 2005; Winslow and Insel 2002). USVs are also emitted during juvenile interactions, by resident females in a resident-intruder task and by males exposed to a female in estrus or their urine (Bozdagi et al. 2010; Panksepp et al. 2007; Wöhr et al. 2011). Analysis of USV spectrograms (shown in Fig. 4) has allowed researchers to identify discrete categories of ultrasonic calls in mice (e.g., Panksepp et al. 2007; Scattoni et al. 2008; Scattoni et al. 2011). Simultaneous recording of social interactions and USVs have revealed correlations between call emission rates, types of calls emitted, and various social behaviors, suggesting that USVs might convey communicative information during social situations (Panksepp et al. 2007; Scattoni et al. 2011). However, much work remains to be done in order to determine the potential communicative value of rodent USVs and their relevance to the types of communication impairments seen in autistic individuals.

Repetitive Behaviors and Resistance to Change in Routine

Several assays are available to investigate behavioral phenotypes in rodents relevant to the third DSM-IV diagnostic criterion of autism, stereotyped, repetitive behaviors, and patterns with restricted interests or activities (American Psychiatric Association 1994; Lord et al. 2000). Rats and mice display spontaneous motor stereotypies that appear to have no specific function, including circling, back flipping, jumping, and cage bar biting (DeLorey et al. 2008; Hines et al. 2008; Lewis et al. 2007; Ryan et al. 2010). Repetitive behaviors in rodents, which may appear as normal patterns but persist for unusually long periods of time, include self-grooming (shown in Fig. 5a) and marble burying (McFarlane et al. 2008; Ryan et al. 2010; Spencer et al. 2011). Resistance to change has been modeled in rodents using reversal learning tasks, which measure perseverative behavior patterns (Moy et al. 2007, 2008b; Nakatani et al. 2009). Reversal learning tasks measure the flexibility of the animal to switch from an established habit to a new habit. Animals are first well-trained to form a spatial position habit, for example, by placing a food reward in the left arm of a standard T-maze or by placing the escape platform into one quadrant of the Morris water maze (shown in Fig. 5b). The location of the food reward or escape platform is then changed, requiring the development of a new position habit. Successful acquisition of the initial position habit but failure to develop the new one might be analogous to insistence on sameness and inflexibility in routines that

is characteristic of autism (Moy et al. 2008b; Nakatani et al. 2009). Tasks relevant to restricted interests or activities are still under development. One approach measures restricted exploration of only one of the available holes in a hole board (Moy et al. 2008a) or only one of several novel objects in an open field (Pearson et al. 2010).

Associated Symptoms

Additional associated symptoms, which occur in some cases of autism, include intellectual impairments, anxiety, sleep disturbances, aggression, clumsiness, idiosyncratic responses to sensory stimuli, and seizures (Dawson et al. 2002; Lord et al. 2000; Piven et al. 1997). In order to more fully characterize a proposed animal model of autism, it is useful to include behavioral tasks which address phenotypes relevant to these associated symptoms (reviewed in Crawley 2007a, 2007b). Standard tasks available for rats and mice are well-characterized in the behavioral neuroscience literature. Learning and memory tasks (e.g., Morris water maze, contextual and cued fear conditioning, novel object recognition) can be used to detect cognitive deficits that may be relevant to the symptom of mental retardation. Tasks used to assay anxiety-related behaviors (e.g., elevated plus maze, light $\leftrightarrow$ dark exploration) can be used to detect high or low levels of anxiety in an animal model. Disturbances in sleep patterns can be evaluated using electroencephalography (EEG) recordings, circadian running wheels, and home cage monitoring systems. Resident-intruder tasks can be used to measure aggressive behavior

Animal Models, Fig. 5 (a) A BTBR T + tf/J mouse engaged in repetitive self-grooming. Photograph contributed by Dr. Mu Yang, Laboratory of Behavioral Neuroscience,

NIMH. (b) Morris water maze for measuring reversal learning, which evaluates resistance to change an established position habit. (Photograph contributed by the authors)

in males. Motor clumsiness can be tested using the balance beam, rotarod, and footprint tests. Sensory hypersensitivity or hyposensitivity can be detected through the acoustic and tactile startle tests, as well as tests that measure pain sensitivity (e.g., hot plate, tail flick). Spontaneous seizures, audiogenic seizures induced by loud tones, or drug-induced seizures induced by administration of convulsants can be measured using observer scoring or EEG recordings. A potential pitfall of detecting phenotypes relevant to the associated symptoms of autism is that they may complicate interpretation of phenotypes directly relevant to a diagnostic symptom. For example, a mutant mouse line with high-anxiety-like behavior would likely display low levels of exploratory activity in the three-chambered social approach task, confounding interpretation of their social approach behavior. This issue requires careful consideration for each animal model in which autism-relevant behavioral phenotypes have been detected.

Control Parameters

When investigating autism-relevant behavioral phenotypes in animal models of ASDs, it is essential to control for physical disabilities that could produce false positives in many of the behavioral tasks described here (Crawley 2007a). For example, a mutant mouse line with a gene mutation affecting olfactory functions could show deficits on social tasks based on successful detection of conspecific odors. Similarly, rats or mice treated with a drug that produces sedation will likely show impairments in social, cognitive, or motor tasks that are attributable to low overall activity as opposed to a reduction in reciprocal social interactions or a learning deficit. To rule out these types of artifacts, potential rodent models of autism must be evaluated on a series of tasks measuring general health, neurological reflexes, sensory abilities, motor functions, and home cage behaviors (Crawley 2007b).

Future Directions

Autism is a complex disorder with variable symptoms, some of which may be uniquely human. For

example, deficits in theory of mind, or the ability to intuit what another person is thinking or feeling, may be difficult to model in nonhuman animals. However, recent reports suggest that mice display empathy-like behaviors following exposure to cagemates who have experienced a painful stimulus (e.g., Chen et al. 2009). Subtle language and communication deficits, such as the inability to understand humor or sarcasm, are unlikely to be successfully modeled in animals. However, detailed analysis of rodent ultrasonic vocalizations may provide information about their communicative value (Lahvis et al. 2011). Modeling complex cognitive abilities, such as executive functions and joint attention, is also a challenge. Researchers are starting to develop cognitive tasks that evaluate sustained attention and attentional set-shifting abilities in rodents similar to those used to evaluate cognitive abilities in autistic individuals (Brigman et al. 2005).

The occurrence of autism is significantly higher in males than in females, with a male to female ratio of 4:1 (Volkmar and Pauls 2003). Thus, an animal model that displays relevant phenotypes in males but not females could be considered to have face validity with regard to the prevalence of ASDs. Due to the higher prevalence of autism in males, many studies have only tested male animals (e.g., Bolivar et al. 2007; Hines et al. 2008; McFarlane et al. 2008; Moy et al. 2007, 2008b; Nakatani et al. 2009; Pearson et al. 2010; Peca et al. 2011), precluding detection of possible sex differences. However, sex differences have been reported for a few animal models of autism. For example, social deficits have been detected in male but not female mice of the inbred C58/J strain (Ryan et al. 2010) and in male but not female rats exposed prenatally to valproic acid (Dufour-Rainfray et al. 2011). Other studies have tested both males and females and detected autism-relevant behavioral phenotypes in both sexes (e.g., Brodtkin et al. 2004; Cheh et al. 2006; Etherton et al. 2009; Moy et al. 2004; Scattoni et al. 2011). Systematic investigations of sex differences in potential animal models of autism will likely lead to a better understanding of the etiology of ASDs.

Despite these challenges, animal models of autism have been useful for evaluating potential

treatments. Early behavioral interventions have been the most effective treatments for the symptoms of autism (Rogers and Vismara 2008). Medications have been reported to improve associated symptoms of autism such as hyperactivity or mood, but have not been shown to affect the diagnostic features of autism. Both pharmacological and behavioral intervention strategies have been tested in mouse models such as the BTBR T + tf/J strain, which displays behavioral phenotypes relevant to all three diagnostic symptoms of autism (Bolivar et al. 2007; McFarlane et al. 2008; Pearson et al. 2010; Scattoni et al. 2008, 2011). A single injection of the drug 2-methyl-6-(phenylethynyl)pyridine (MPEP), a potent antagonist at mGluR5 subtype glutamate receptors, significantly reduced repetitive self-grooming in BTBR mice (Silverman et al. 2010). Rearing BTBR mice with social C57BL/6J mice as cagemates after weaning significantly improved their sociability in the three-chambered social approach task as adults (Yang et al. 2011a). Several potential drug candidates, such as other mGluR5 antagonists, rapamycin, brain-derived neurotrophic factor (BDNF), and oxytocin, have been shown to prevent or reverse aberrant phenotypes in a variety of mouse models of ASDs (reviewed in Silverman et al. 2010). Animal models with robust and well-replicated behavioral phenotypes will be powerful tools for developing pharmacological and behavioral treatments for autism.

Anime, Manga, and the Etiology of Autism

Wassim Hassan

Department of Neuroscience, Perelman School of Medicine at the University of Pennsylvania, Philadelphia, PA, USA

Historical Overview

The origins of Anime and Manga are difficult to pinpoint. According to some historians, the earliest form of sequential art in Japan emerged in twelfth-century Buddhist scrolls, the most famous of which were created by a monk named Bishop Toba (Brenner 2007). These scrolls were originally created to express religious messages and folklorish narratives. Largely unknown by the general body of society, they soon made their way into popular culture. This form of art went through a series of changes over the next few centuries, eventually entering the scope of entertainment. Illustrators sought to present cartoons in the same fashion, leading to the birth of modern day comics.

The term “Manga” was coined by artist Hokusai Katsuhika in the nineteenth century, which literally means “whimsical pictures” or “sketches.” Bound books with intricate story-lines were soon produced and sold by the thousands. However, the content within the books was considered to be adult in nature and was therefore banned by the Tokugawa regime (Horbinski 2015). The era of modern Anime and Manga would soon be ushered in by the forces of globalization. With Japan’s historically isolated nature dwindling, the advent of modern technology would completely change the trajectory of Anime and Manga.

The arrival of US Commodore Matthew Perry on Japanese shores catalyzed drastic changes in Japan, with a brutal internal struggle between traditional isolationists and those who embraced the West overtaking the entire country. Eventually, Japan would succumb to the influx of the Western way of living, struggling to update its society with technological advances among other

changes. Japanese artists were fascinated by Western forms of art, and eventually created a hybrid that took the form of modern day Manga magazines. The initial forms of Manga magazines were either politically oriented or meant for children. By the middle of the twentieth century, a new genre emerged. Adult Manga comics captivated the entire industry, with explicit representations of crime, sex, and violence. As a result, the more innocent renditions of Manga comics lost business and dwindled in their prevalence.

The development of Anime and Manga snowballed quickly, with comics progressing into television shows, movies, and trading cards. The most significant changes, however, were arguably seen in the fanbase of the genre. Previously aimed at a politically inclined audience as well as children, Anime and Manga morphed into something of a lifestyle for its fans – of all ages, especially adults. One interesting phenomenon in particular is that of cosplay, a play on the words “costume” and “play.” The past few decades have seen cosplay fans gather from all over the world, spending inconceivable monies on intricate costumes and, in some cases, plastic surgery, to resemble their favorite Anime and Manga characters (Winge 2006). These subcommunities of the general Anime genre have experienced significant stigmatization in popular culture.

Among the main factors stigmatizing Anime and Manga fanbase is the reality that the overwhelming majority of amateur Manga artists focus on producing homoerotic and other sexually explicit depictions. As a result, the fanbase became subject to significant controversy in the 1990s (Kinsella 1998). Further, the sheer obsession that Anime and Manga fans hold for their genre of interest is seemingly beyond any other fanbase. With other forms of entertainment typically remaining in the realm of a hobby, Anime and Manga seemed to have a tendency to categorically consume fans. Drastic changes in behavior, dress, speech, lifestyle, spending habits, and other intimately characteristic facets of individuality are not uncommon among fans of Anime and Manga. Anime and Manga fans call themselves “Otaku,” more commonly known with a more general term: “Hikikomori.” Otaku refers to, usually male,

Japanese fans between ages 18 and 40 that fanatically and compulsively consume Anime and Manga products (Azuma 2009). Originally a group of social outcasts bonding over a shared interest, the Otakus now represent a massive portion of the commercial market in Japan.

Of the peculiarities of this demographic is the tendency of psychological uniformity among many of the fans. There exists a surprisingly common set of characteristics among a large portion of Otakus. Researchers have found that there seems to be a surprising association between individuals with autism spectrum disorder (ASD) and the Otaku demographic. While Otakus are often not officially diagnosed as autistic, the culture surrounding Anime and Manga has been called “autism-friendly” (Cowen 2010). The link between Anime, Manga, and ASD begs the question: should this raise any concerns?

Current Research

The affinity that patients with autism spectrum disorder (ASD) have for Anime and Manga products is not an unknown phenomenon to clinical psychologists and therapists. A study carried out with 91 randomized adolescents with ASD found that among the most often visited websites by the subjects fell into the category of anime (Kuo et al. 2013). In fact, this was the second most commonly explored activity among the participants. This is a peculiar pattern, given that individuals with ASD typically exhibit extremely restricted interests (Koegel et al. 2015). High school students with ASD have also been found to gravitate towards only a handful of interests, one of which is the anime fandom (Wolf et al. 2009).

ASD symptoms in adults present in a fairly consistent manner. Common behaviors include preference for social isolation, stunted communication skills, compulsive behavior, difficulty recognizing verbal cues, restriction to either obsession or passiveness towards things, and highly animated approaches to social settings that may include aggression or overly indifferent behavior (*Mayo Clinic*). These behaviors are not alien to the average Otaku. In fact, the

characteristics of Otakus are not much different from the manner in which higher functioning individuals with ASD are described in the West (VanBergeijk 2010).

A study focusing on the Hikikomori (a general term encompassing Otaku) subset of individuals found that about 20% of their Hikikomori patients could be diagnosed with pervasive developmental disorders, or PDD (Tateno et al. 2012). Diagnosis of PDD typically takes place once qualitative impairment in social interaction and restricted and compulsive patterns of behavior and interests are observed in a patient. This is commonly seen in Hikikomori and Otaku. Thus, diagnosis of PDD, especially ASD, should be seriously considered in Hikikomori and Otaku patients. The reality is that ASD is only known by the symptoms exhibited in individuals that have it. There is no biological or genetic factor that has yet been clearly identified by the scientific community (Rozema 2015). This limits our understanding of ASD significantly. Consequently, the etiology of ASD is still unexplored territory. Because the Otaku community heavily exhibits symptoms of autism, a potential environmental etiology must be considered (Vuković 2014).

Future Directions

Why individuals with ASD love Anime and Manga is largely unexplored territory. Robert Rozema mentions that it is estimated that 1 in 68 children fall on the autism spectrum (Rozema 2015). With such a high prevalence, it is important to study the behavioral patterns of this demographic to achieve a firmer understanding of both ASD and the effects of Anime and Manga on a sociological and pathological level. Furthermore, researchers much approach the topic with an open mind, ready to reexamine previously held conceptions about ASD.

The etiology of ASD is still a topic of debate and scarce research. As mentioned, an Otaku is virtually indistinguishable from a high functioning individual with ASD. It is not inconceivable that the captivating tendencies of Anime and Manga produce individuals that operationally

fall on the autism spectrum. In other words, they may not traditionally have ASD as we understand it, but they have grown to develop the same symptoms by way of their fanatical obsession with Anime and Manga products. The umbrella that is ASD, understood to develop in the earliest stages of childhood, must perhaps be expanded to accommodate those adults that develop the same behavioral characteristics later on.

Additionally, the phenomenon of Otaku culture is viewed by many to be a pathological epidemic that is crippling an entire generation. The erosion of social skills, restriction of interests, and displaying of obsessive behaviors are all detriments to the mechanics of day-to-day life. Given the rapidly expanding market for Anime and Manga products as well as the proliferating fanbase, sociologists must allocate efforts towards studying the societal effects of Otaku culture on the development of youth. If the development of the fanbase in the West is towards the same trajectory as Japan, the impacts would be immense in the academic system, the corporate world, the fields of social work and therapy, as well as the structure of society as a whole. The relationship between Anime, Manga, and Autism is one of massive potential in understanding the etiology of ASD and perhaps curbing a looming social epidemic.

Definition

The annual review is a formal meeting required by Individuals with Disabilities Education Act (IDEA) and conducted by the school to develop, review, or revise a student's Individualized Education Program (IEP). IEPs also can be reviewed and revised any time during the year but have to be reviewed and updated at least once per year. The purpose of the annual review is to evaluate and revise the basic educational program, instructional guide, placement, services, and, when the child is 14 or older, a transition plan. The participants include the child's educational team members (e.g., the student [when appropriate], both parents, case manager, child's teachers, a school representative other than

the child's teacher, and others can be invited at the discretion of the parents or the district board of education). Schools must provide parents with advanced notice in writing of the annual review meeting. During the meeting, team members review the child's present level of functioning, progress in the general curriculum and towards IEP goals and objectives, and student needs. Teachers should provide progress-monitoring data for each of the goals and objectives; this should include indicating if the goal is met, partially met, or unmet with specific descriptions and explanations as necessary. Also, the team members make recommendations for the next year's program based on the child's needs and progress with current goals and objectives. These include identifying new goals and objectives, determining the necessary levels and types of support for the child to meet IEP goals, and considering and explaining placement options.

Antecedent-Behavior-Consequence (A-B-C) Analysis

Kathleen Dyer

River Street Autism Program at Coltsville,
Capitol Region Education Council/Elms College,
Hartford, CT, USA

Endicott College, Bloomfield, CT, USA

Definition

An A-B-C analysis is a descriptive assessment that is conducted as an initial part of a complete functional behavior assessment. The goal of this analysis is to develop hypothesis regarding the function that a problem behavior serves for an individual with ASD. A-B-C analysis views behavior (B) as a function of the antecedents (A) that precede it and the consequences (C) that follow it. Typically, an A-B-C chart is used over an extended time period to record events that occur naturally rather than being systematically arranged. These events occur in the natural environment, with the observer recording the environmental events that occur immediately before the behavior in the (A) section, the specific behavior observed in the (B) section, and the events occurring immediately after the behavior in the (C) section.

Historical Background

A-B-C analysis began in the 1960s with the beginnings of applied behavior analysis, with Sidney Bijou and colleagues asserting the importance of collecting direct and repeated data on the observable interactions between the behavior exhibited by the organism and the events in naturally occurring conditions. Interrelationships between the behavior and past and future events were the primary data of interest. The first step of the analysis was a narrative recording, which was a running description of occurrences during an observational period, with no specific behavior targeted for observation. These

descriptions were the first step in identifying a targeted behavior that would be measured formally in further analysis. These temporally sequenced events were translated into A-B-C forms that specified each behavior of interest and the events that occurred immediately before and after the behavior.

In the 1970s, research conducted by Edward Carr and colleagues found that many problem behaviors were logically linked to a small set of antecedents and consequences. Specifically, these researchers stated that an individual with ASD usually exhibited problem behavior to either gain access to attention or a desired item or to escape an undesired event. With the growing body of research studies that supported these findings, the focus of A-B-C analysis narrowed. Currently, many A-B-C analyses focus on more severe problem behavior, such as self-injury, aggression, tantrums, and pica. Antecedent conditions usually consist of (1) demands, (2) attention removed, (3) preferred activity removed, and (4) alone. Similarly, consequence events that follow the problem behavior are often restricted in focus to (1) attention provided in the form of reprimands or soothing statements, (2) removal of demands, (3) access to preferred items, or (4) problem behavior is ignored or neutrally redirected. In addition, initiation of the A-B-C analysis is triggered by concerns regarding the problem behavior voiced by clinical or educational team.

Current Knowledge

The customary usage of the A-B-C form is as one component of a complete functional behavior assessment of a problem behavior exhibited by the individual with ASD. However, these forms can be used for any socially significant behavior of interest. A-B-C forms can be open-ended, where the observer fills in any event that occurs before or after the behavior. Some A-B-C analyses specify time frames and define “immediately” specifically (e.g., as 20 s before or after the behavior occurs).

The categories to be completed in the observation are:

1. The observable behaviors (B) exhibited by the individual with ASD. When defining behavior, it is important to provide clear criteria of the behavior. (e.g., tantrums might be distinguished from whining or crying by being described with an intensity and duration measure, such as screaming and loud crying, that lasts more than 30 s. In addition, tantrums co-occur with one of the following behaviors: lying on the floor, kicking legs, and/or swiping materials off desk). It is also important to record the extent to which the behavior co-occurs with other behaviors in a sequence. Such a sequence might be, for example, first, crying; second, falling on the ground; and third, throwing large objects at adults.
2. Antecedent events (A's) that immediately precede the behavior.
3. Consequent events (C's) that immediately follow the behavior. The consequent events customarily recorded are the social behavior of the adult that is interacting with the individual and include behaviors such as providing attention, feedback, reprimands, access to preferred items/events, and ignoring.

It is also important to include information regarding the setting, other persons present, and materials available and include any other information that may be relevant, such as time of day, day of week, and any unusual events that may effect behavior.

Information gathered from A-B-C analysis is used to develop hypothesis regarding the function (motivation) of the problem behavior and then develop subsequent treatment plans based on this information.

Use of A-B-C forms requires training of observers to limit their recordings to observable and measurable behaviors, as untrained observers have been reported to include subjective impressions of thoughts and feelings of the person observed. This might lead to instances of recording impressions such as “frustrated,” “mad,” “agitated,” or “sad.” In addition, sensitivity to the types of environmental events needs to be trained. It is not uncommon for an untrained observer to record “nothing” as an event, and training on specificity of events to include aspects such as

physical environment, persons present, and materials available is necessary.

Narrative Recordings

These recordings included a description of the setting, time, people present, and materials available. The evaluator begins with a running narrative description of the individual’s behavior, such as “Ed is playing alone in the block center.” When the teacher says “Time to come to circle,” Ed continues to play with the blocks, and the teacher starts the circle without him. When the Aide taps Ed on the shoulder and says “Ed, it’s time to go to circle,” Ed throws the block at the aide. The aide then leaves Ed to play with the blocks, and the teacher conducts circle time with the other children. Here is sample sequence analysis of this recording into a three-column form of antecedents (A), behaviors (B), and consequences (C).

Antecedent (what happened right before the behavior occurred?)	Behavior (record the behavior here)	Consequence (what happened right after the behavior occurred?)
	Ed is playing in the block center	
Teacher says “It’s time for circle”	Ed continues to play with blocks	Aide taps Ed and asks him to join the circle
Aide taps Ed and asks him to join the circle	Ed throws block at aide	Aide leaves Ed alone
Aide leaves Ed alone	Ed plays with blocks	Teacher and aide conduct circle without Ed

The analysis is restricted to describing the participant’s behavior and excludes conjecture regarding the participant’s thoughts and feelings.

For example, “He hits other children because *he does not understand* the situation” would not be included in the analysis, as *understanding* is not observable or measurable behavior. Finally, in A-B-C analysis, generalizations are not made about the environment and behavior, such as “He is a trouble maker who always gives the teacher a hard time.” Finally, in this analysis, consequent events for one behavior can turn into antecedent events for the following behavior.

Open-Ended A-B-C Recording

In this type of analysis, the narrative recording is omitted. The observer uses the A-B-C form when the specific targeted behavior occurs and records the antecedents and consequences that come before and after the targeted behavior. It is recommended that observers include the time the behavior started and ended, the intensity of the behavior, and any other important characteristics of the setting. An example of a form for this type of recording is in Table 1.

Specific A-B-C Recording

In this type of A-B-C analysis, the observer is provided with a specific checklist of A-B-C events to record in a specific ongoing time period. For example, the time period might consist of a 1-h block in the morning, and the observer would record specified behaviors that occurred during that time. In addition, the specified antecedents are recorded whether or not they were followed by problem behavior. This is distinguished from the open-ended recording described above that is only used when the targeted behavior occurs. This type of recording allows a more fine-tuned analysis of the relationship between the antecedent and behavior, as it would detect conditions where the antecedent occurred and the behavior did not

Antecedent-Behavior-Consequence (A-B-C) Analysis, Table 1 Open-ended A-B-C form

Antecedent (what happened right before the behavior occurred?)	Behavior (record the behavior here)	Consequence (what happened right after the behavior occurred?)	Comments
Ex. Teacher said “Time for math” while placing worksheet before student	Ex. Kicked teacher	Ex. Teacher says “It looks like you’re not ready for work” and takes worksheet and walks back to desk	

follow, ruling out faulty correlations between antecedents and consequences.

The specific events recorded can be developed from preliminary information gathered from interviews and/or narrative recordings (see above). The following are possible specific antecedents, behaviors, and consequences used on these forms:

Antecedents

- Demand
- Request
- Feedback
- Denial
- Reprimand
- Transition
- Alone
- Removal or diversion of adult attention
- One-to-one instruction
- Group instruction
- Physical contact
- Social interaction
- Engaged in preferred activity

Behaviors

- Aggression
- Tantrums
- Self-injury
- Bolting
- Pica
- Loud vocalizations
- Stereotyped behavior
- Noncompliance
- Throwing
- Property destruction

Consequences

- Attention
- Corrective feedback
- Access to preferred item
- Ignoring or redirecting behavior
- Task demand
- Task removed
- Physical contact
- Soothing
- Automatic reinforcement (self-stimulation)
- Reactive behavior management procedure

- Time out
- Overcorrection
- Response cost
- Contingent exercise

While the above list provides broad categories of environmental conditions to be analyzed, more fine-grained analysis is often warranted. For example, “task demand” can be specified further as follows:

- Task demand
 - Instruction provided with only auditory cues
 - Instruction with auditory and visual cues
 - Instruction with only visual cues
 - Instruction with auditory, visual, and tactile cues

Or

- Task demand
 - Math task
 - Art task
 - Writing task
 - Expressive speech task

The important point to remember is that the A-B-C analysis should be provided with enough specificity to identify the relevant variables that trigger and maintain the problem behavior. If a student will play with all toys with the exception of puzzles, this should be specified in the analysis.

The sample form in Table 2 lists specific categories of antecedents, behaviors, and consequences for the observer to check off. Using this form, the observer records the antecedent events as they occur, even if the problem behavior does not occur after the antecedent.

After the data are collected, summary statements are developed for each major antecedent or consequence of the behavior and hypotheses are generated regarding the function of the problem behavior.

Future Directions

While there is a growing body of peer-reviewed research studies that shows that while the data

Antecedent-Behavior-Consequence (A-B-C) Analysis, Table 2 Specific A-B-C recording form

Antecedent (circle antecedent)	Behavior (circle behavior)	Consequence (circle consequence)
Demand/instruction	Self-injury	Provide adult attention
Transition	Aggression	Give preferred item or activity
Playing alone	Tantrums	Remove adult demand
Adult attention removed		Provide adult attention
Restrict access to preferred item/activity		Adult reprimand

Repeat above		

collected from A-B-C observations is useful, additional studies have asserted that functional analysis is a more reliable method of identifying variables that control the behavior, and therefore, manipulating these variables lead to more successful treatments. It is therefore recommended that information gathered from the descriptive A-B-C analysis be used as an initial information-gathering step that precedes a formal functional (experimental) analysis. There is controversy regarding this recommendation, as it is argued by some that the information from the A-B-C analysis is sufficient to form hypothesis regarding the motivation of problem behavior that can lead to effective treatments. The time, cost, and controlled clinical settings required to conduct a thorough functional analysis is often not available in customary educational and clinic settings where treatment is provided.

Current A-B-C analyses are restricted to recording observable events in the environment that may predict the occurrence of problem behavior. These events are restricted to immediate antecedents and consequences, which have been referred to as *near triggers*. Future analysis are taking into account *far triggers* such as lack of sleep, a death in the family, moving residences, or other changes in events that may not be immediately apparent in the A-B-C setting. It is recommended to use equipment to measure biological variables, such as increased or decreased heart rate, the need to urinate, physical pain, and

low blood sugar when identifying predictors of problem behavior in the future.

It is argued that underlying characteristics of the individual with ASD can also be strong predictors of behavior. These can include deficiencies such the ability to process complex auditory information, cognitive limitations, and difficulty with abstract reasoning. In addition, the effects of anxiety and mood disorders could be considered as contributing factors to behavior.

ACC

Structure

The anterior cingulate cortex (ACC) is in the frontal portion of the cingulate cortex, situated medially just above the corpus callosum. The ACC consists of Brodmann areas 24, 25, 32, and 33. Vogt and colleagues (Vogt 2009) defined four major subdivisions of the rostral ACC. These include a supracallosal portion (above the corpus callosum), designated “midcingulate cortex,”

which is divided into an anterior and a posterior portion. The aspect of the cingulate lying anterior and ventral to the corpus callosum is designated “anterior cingulate.” This region is further divided into a pregenual region (more anterior) and subgenual region (more ventral). Based on observed functional differences (Bush et al. 2000), neuroscientists often distinguish between a “cognitive” dorsal portion of the ACC and an affective ventral portion of the ACC. The dorsal ACC is connected to the prefrontal, parietal and motor cortices, and motor and frontal eye fields whereas the ventral ACC is connected to the more traditional limbic regions including the amygdala, nucleus accumbens, anterior insula, and hypothalamus. More recently, Shackman et al. (2011) provided a coordinate-based meta-analysis of neuroimaging studies suggesting the cognitive-affective demarcation of the ACC is less clear-cut than was originally assumed.

Function

The anterior cingulate’s functions are diverse, including the cognitive control of motor behavior in response monitoring (Botvinick et al. 2001; Devinsky et al. 1995; Holroyd and Coles 2002), reward-based learning (Holroyd & Coles), registering physical (Craig et al. 1996) and social pain (Eisenberger and Lieberman 2004), empathy, consciousness, and autonomic functions.

The ACC is implicated in the related processes of conflict monitoring, response inhibition, and error detection. On simple behavioral paradigms such as the Stroop color word interference task, the individual is charged with responding to the color of a word when the word color differs from the written word (e.g., the word blue written in yellow text). In this task conflict is engaged because the automaticity involved in reading the word conflicts with the different color of the printed word. However, the ACC has been shown to be activated independently of the presence of response alternatives on a Stroop-like task suggesting a role as a top-down regulator increasing the amount of “top-down” regulation required to meet the task demands (Roelofs et al. 2006). In

doing so, the ACC would selectively enhance the activation of a correct response pending some selection threshold to be exceeded (Roelofs et al. 2006). The incorrect response must be inhibited in favor of the correct response. If an incorrect response is executed, it needs to be detected to adjust performance accordingly. In this process, the ACC appears to be involved in error detection, regardless of whether or not errors are consciously perceived, and in the perception of errors committed by others (Gentsch et al. 2009; Hester et al. 2005; Holroyd et al. 2004; Klein et al. 2007; Ullsperger and von Cramon 2001; Ullsperger et al. 2007).

The role of the ACC in response monitoring and reward processing has been linked in a general reinforcement model that attempts to account for error processing, feedback processing, and reinforcement learning more generally. Here, the dorsal ACC is thought to use reward prediction error signals, conveyed via the mesencephalic dopamine system, to reinforce adaptive behavioral responses (Holroyd and Coles 2002). As noted by Holroyd and Coles (2008), two general types of theories have been proposed to describe the role of the dorsal ACC in response monitoring processes. Some theories propose the ACC serves an evaluative role to detect errors or conflict. The response selection perspective suggests ACC is directly involved in the decision making process (Holroyd & Coles). Other neuroimaging work implicates the ACC, but not specifically the dorsal ACC in outcome anticipation, uncertainty of outcome (Critchley et al. 2001a), subjective value of potential rewards (Kable and Glimcher 2007), and imagined or “fictive” rewards (Hayden et al. 2009).

A growing body of work implicates the ACC in physical pain, social pain, and empathy-related processes. In terms of physical pain, recent neuroimaging work indicates the ACC is associated with the unpleasantness aspect of physical pain (Rainville et al. 1997). Studies of social exclusion, a socially painful experience, indicate that some of the same neural circuitry, including the ACC, is involved in the distressing aspect of being excluded by others in a group (Eisenberger and Lieberman 2004). Among typically developing adolescents, neural response to social rejection engages brain

regions involved in affective distress (subgenual anterior cingulate, anterior insula) and affect regulation (ventrolateral PFC, ventral striatum) (e.g., Masten et al. 2011; Sebastian et al. 2011). Interestingly, the anterior cingulate cortex is part of a network consistently engaged in studies of empathy for others’ pain (Krach et al. 2011).

The ventral ACC has been implicated in emotion processing (for reviews see Bush et al. 2000; Shackman et al. 2011). The ventral ACC has been shown to be engaged in modulation of the sympathetic as well as the parasympathetic aspects of the autonomic nervous system (Critchley et al. 2001b; Matthews et al. 2004). As part of a network of higher cortical structures including the insula, amygdala, and hippocampus, the ventral ACC is connected to lower structures that have been dubbed the central autonomic network (Benarroch 1993).

Pathophysiology

Emerging evidence at the levels of cell microstructure, neuronal connectivity, and brain volume suggest abnormalities in the ACC of people with an autism spectrum disorder (ASD). In post-mortem work, Simms and colleagues (Simms et al. 2009) observed that individuals with autism had smaller neurons and reduced neuronal density in the ACC. They specifically examined von Economo neurons (VENs). Interest in VENs in ASD has burgeoned recently given their putative role in emotional regulation and social interaction (Allman et al. 2005; Allman et al. 2010). Simms et al. (2009) found that while VENs did not differ from control brains overall, a subset of ($n = 3$) ASD individuals had significantly increased VEN density whereas the remaining six individuals had reduced VEN density compared to controls. Suda et al. (2011) recently documented the expression of axon guidance proteins were significantly lower in the ACC region among autistic individuals compared to controls (Suda et al.). Similarly, in an examination of ACC single cell axons in brain white matter, Zikopoulos and Barbas (2010) found evidence for a decrease in long axons that communicate over long distances and an

excessive number of thin axons linking the ACC to neighboring areas. Other work points to the role of GABAergic (gamma-aminobutyric acid) function in the ACC in ASD (Zikopoulos and Barbas). GABAergic neurons have chiefly inhibitory action at receptors in the brain. GABA is important for normal cortical functioning, information processing, and cytoarchitecture during brain development (Di Cristo 2007). For instance, in a pair of studies Oblak, Gibbs, and Blatt (2009, 2010) observed reductions in GABA_A and GABA_B receptor densities in the ACC (Oblak et al. 2009, 2010). Lastly, Nakamura et al. (2011) conducted a postmortem study implicating the serotonin (5-HT) system in the ACC to ASD. In the brain, serotonin plays an important role in mood regulation sleep and appetite. Nakamura et al. (2011) observed that the expression of a protein that regulates the serotonin transporter (5-HTT), STX1A, was significantly lower in the ACC region in an autism group compared to controls (Nakamura et al. 2011).

In vivo research documents altered ACC cell membrane metabolism (Levitt et al. 2003). Employing positron emission tomography (PET), Ohnishi et al. (2000) found decreased left ACC cerebral blood flow (Ohnishi et al.). Similarly, Haznedar et al. (1997) observed reduced glucose metabolism throughout the cingulate gyrus and reduced right ACC volume (Haznedar et al.). Moreover, in the ASD group, glucose metabolism was positively associated with social interaction, verbal communication, and nonverbal communication scores.

In terms of connectivity with other brain regions, Welchew et al. (2005) observed atypical connectivity of the ACC with inferior occipital and inferior frontal cortices (Welchew et al.). In the first study using diffusion tensor imaging in ASD, Barnea-Goraly et al. (2004) observed that ASD children had reduced ACC fractional anisotropy (FA), a measure thought to reflect fiber density, axonal diameter, and myelination in white matter, extending to adjacent regions including the ventromedial frontal area and subgenual prefrontal region, bilateral temporoparietal junctions, and adjacent superior temporal gyrus (Barnea-Goraly et al.). Similarly, Noriuchi et al. (2010)

observed that FA was significantly lower in a child ASD group in the mid and right ACC among other regions (Noriuchi et al.). Using diffusion tensor imaging, Ke et al. (2009) observed decreased white matter density in a high-functioning autism group in the right frontal lobe, left parietal lobe, and right anterior cingulate and increased white matter density in the right frontal lobe, left parietal lobe, and left cingulate gyrus compared to control children (Ke et al.). Lastly, in terms of grey matter, Waiter et al. (2004) documented an increase in grey matter volume in the ACC among male adolescent ASD subjects (Waiter et al.).

A growing number of studies find individuals with ASD have deficits in response monitoring. Response monitoring is an executive task subserved by the ACC. Response monitoring specifically refers to evaluating whether one's actions are consistent with one's goals and modifying behavior accordingly to optimize outcomes. In a recent fMRI study, Thakkar et al. (2008) used a performance monitoring task finding that individuals with ASD had increased rostral ACC activation which was related to repetitive behaviors (Thakkar et al.). In terms of behavioral responses, Russell and Jarrold (1998) reported reduced error self-correction among adults with ASD (Russell and Jarrold). Bogte, Flamma, van der Meere, and van Engeland (2007) observed reduced post-error slowing in ASD, an index of behavioral correction to improve performance on a subsequent trial (Bogte et al. 2007). In one of the first ERP studies suggesting abnormal response monitoring in high-functioning ASD, Henderson et al. (2006) observed increased latency in the ERN event-related potential response, and poorer behavioral performance overall. ASD children did not differ from comparison children in terms of ERN amplitude, but ASD probands with higher IQs showed significantly larger ERN responses, suggesting hypersensitivity to errors among this group. In a second study with ASD children, Vlamings, Jonkman, Hoeksma, van Engeland, and Kemner (2008) observed smaller ERNs and a lack of post-error slowing behaviorally (Vlamings et al. 2008). The authors observe this finding, coupled with a comparable correct trial negativity (CRN) for

ASD and typical children is consistent with perseverative behavior seen in ASD children (for a similar finding in adults see Santesso et al. (2010)). Interestingly, a recent study employing a reward-loss feedback task did not find differences in a related brain response thought to be subserved by the ACC, the feedback-related negativity (FRN) (Larson et al. 2011). These data suggest that individuals with ASD process external, concrete feedback similarly to typically developing individuals.

Not surprisingly, anterior cingulate dysfunction also continues to emerge when the experimental paradigm involves social functioning. A meta-analytic examination of 24 studies on social information processing and 15 nonsocial studies by Di Martino et al. (2009) suggests that a distributed system involving the ACC and the anterior insula was hypoactive for individuals with autism – in nonsocial studies the ASD individuals were more likely to show activation in the rostral ACC, which is typically suppressed in attention-demanding tasks. Importantly, we see deficits in the functioning of this specific circuitry in social challenge tasks such as social rejection/exclusion paradigms. Compared to controls, children and adolescents with ASD showed hypoactivation in the ventral ACC and right insula when they were excluded from a simple computer game by same-aged peers (Bolling et al. 2011; Masten et al. 2011).

Other recent social-cognitive work employing experimental paradigms seems to tap monitoring processes as described above, but social monitoring in particular. Recently, Chiu et al. (2008) provided evidence that atypical neural self-representation in ASD involves the cingulate cortex. In typical adolescents and young adults, self-referential compared with other-referential processing preferentially recruited the middle cingulate cortex and ventromedial prefrontal cortex. ASD individuals did not show this self-referential preference. Instead, ventromedial prefrontal cortex responded equally to self and other, while middle cingulate cortex responded more to other-mentalizing than self-mentalizing (Chiu et al.). Importantly, the lack of cingulate “self” response pattern in the ASD group related parametrically to ASD symptom severity. In another

important study, Kennedy and Courchesne (2008) had autism and control participants make true/false judgments for statements about themselves (“self” condition) or a close other person (“other” condition) and related to psychological personality traits (“internal”) or observable characteristics/behaviors (“external”). Within the ventral medial prefrontal cortex and ventral anterior cingulate cortex, activity was reduced for the ASD group across all conditions and also during a rest condition, suggesting task-independent dysfunction in this region (Kennedy and Courchesne).

While clearly a large amount of data supports ACC involvement in the autism phenotype, the ACC should not be considered the only neural structure relevant to autism pathophysiology. First, the ACC is connected to multiple brain and body systems that may be more or less affected in the disorder (see above). Second, and relatedly, functioning in the ACC contributes to self-regulatory and social cognitive abilities, but in concert with other brain and body systems. Third, functioning in the ACC cannot account for all aspects of the autism phenotype more generally (e.g., language delays). Thus, future work examining ACC function in autism will need to incorporate new developments in our understanding of ACC anatomy and function (Shackman et al. 2011; Vogt 2009) coupled with nuanced and yoked paradigms that can be used to parse ACC-relevant functions (Bolling et al. 2011; Chiu et al. 2008) explicit examination of individual differences (Henderson et al. 2006) and a neural systems perspective (Mundy et al. 2010). There again, autism emerges in a developing organism necessitating developmental studies tracking the course of ACC development against the backdrop of typical ACC development (Pelphrey et al. 2011). As of yet, we do not know whether or not the ACC dysfunction plays a causal role in the emergence of the disorder or is secondary to having the condition.

Antianxiety Medication

► Anxiolytics

Anticholinergic

Lawrence David Scahill

Nursing and Child Psychiatry, Yale Child Study Center, Yale University School of Nursing, New Haven, CT, USA

Marcus Autism Center, Children's Healthcare of Atlanta, Atlanta, GA, USA

Department of Pediatrics, Emory University, Atlanta, GA, USA

Definition

Acetylcholine is a chemical that transmits messages between nerve cells in the brain. Centrally acting anticholinergic drugs block the effect of acetylcholine in the brain. These drugs are used to counteract adverse effects of antipsychotic medications. Acetylcholine is a major neurotransmitter in the brain. Acetylcholine and dopamine are in a dynamic balance in the brain. Because many antipsychotic medications block dopamine receptors in motor regions of the brain, there is a relative excess of acetylcholine. This gives rise to the commonly observed neurological side effects of antipsychotic medications such as tremor, dyskinesia, and dystonia. These adverse effects typically occur early in treatment, are unpleasant, and may pose a serious threat to medication adherence. Anticholinergic medications such as benztropine are often useful in reducing these neurological effects of

antipsychotic medications (link to “Psychopharmacology” section of this encyclopedia).

The anticholinergic drugs can also have adverse effects. In the low doses used to treat neurological side effects of antipsychotic medications, adverse effects are not common. At higher doses, adverse effects can include confusion and memory problems, and hallucinations can occur.

Anticholinesterase Inhibitors

Karthikeyan Ardhanareeswaran

Autism Program, Child Study Center, Yale School of Medicine, New Haven, CT, USA

Program in Neurodevelopment and Regeneration, Yale School of Medicine, New Haven, CT, USA
Department of Molecular, Cellular, and Developmental Biology, Yale University, New Haven, CT, USA

Synonyms

[Acetylcholinesterase inhibitors](#); [AChE-inhibitors](#)

Definition

Acetylcholine (ACh) is a neurotransmitter key in an individual's ability to adapt to his/her environment and surrounding stimuli. ASD patients show many deficits in ACh production and receptor function. Acetylcholinesterase is an enzyme

involved in the degradation of acetylcholine. Anti-cholinesterase inhibitors, or acetylcholinesterase inhibitors (AChE-inhibitors), seek to block the action of this enzyme, thus increasing ACh levels and action durations. Examples that have been tested and shown beneficial effects in ASD patients include rivastigmine, donepezil, and galantamine. Improvements in expressive speech are consistent across the drugs. Reports also include improvements in irritability, hyperactivity, receptive language, social withdrawal, inattention, and anger management. Side-effect profiles include diarrhea, nausea, and vomiting. Currently AChE-inhibitors are some of the most promising class of drugs in treatment of dementia, especially in Alzheimer's disorder, indicating some degree of alleviation in memory dysfunction. They are delivered orally, rapidly absorbed, and metabolized via CYP P450 isoenzymes CYP2D6 and CYP3A4 in the liver. Their relatively minimal side-effect profiles combined with demonstrated slight improvement in ASD symptoms make them an attractive candidate for ASD pharmacology. However, substantial validation of their consistent effectiveness and minimal side effects in ASD patients specifically is still required.

Anticipated Regression

Fred R. Volkmar

Child Study Center, Irving B. Harris Professor of Child Psychiatry, Pediatrics and Psychology, Yale Child Study Center, School of Medicine, Yale University, New Haven, CT, USA

Definition

Under current federal law, and as clarified in several court cases and policy explanations, services for the extended school year (ESY) for children with disabilities (either because they have an IEP or 504 plan) can be provided in some contexts. Historically, the potential for the child to regress (anticipated regression) has been regarded as one of the most relevant of these; even here, however, multiple factors should be taken into account. This regression would typically be defined by a loss of knowledge or skills that reflects an interruption of educational programming, placing the gains the child has made at risk. The factors considered by the IEP team have to do with maintenance of skills as well as the nature and severity of the disability.

Definition

Medications, including monoamine oxidase inhibitors (MAOIs), tricyclic and tetracyclic antidepressants (TCAs), selective serotonin reuptake inhibitors (SSRIs), and serotonin-norepinephrine reuptake inhibitors (SNRIs), used to treat depressive disorders, conditions characterized by depressed mood often along with other symptoms including the following: changes in appetite, changes in sleep habits, low energy, low self-esteem, poor concentration, and feelings of hopelessness.

Historical Background

The first types of antidepressants to be developed, sometimes referred to as the first-generation antidepressants, include the MAOIs and TCAs. The first of the MAOIs to be developed was iproniazid, a drug initially marketed in 1952 for the treatment of tuberculosis. When it was shown

that iproniazid appeared to induce euphoria in patients and reversed the effects of reserpine, a known depressant, Saunders and Kline began using iproniazid to treat clinical depression. Kline published an article on its clinical use for the treatment of depression in 1958. Although its adverse effects caused its use to be discontinued, iproniazid was replaced by other compounds that inhibit monoamine oxidase. However, the MAOIs were found to exhibit adverse reactions with other drugs and amines. The development of the TCAs began at the same time as that of the MAOIs. The first TCA to be developed, imipramine, was tested as a neuroleptic agent when it was found to relieve depressive symptoms. Comparing the mechanisms of action of the MAOIs and the TCAs caused investigators to recognize that increasing the amount of synaptic neurotransmitter was important for the treatment of depression.

SSRIs, considered to be second-generation antidepressants, were developed to have the specific mechanism of action of the inhibition of the reuptake of serotonin (5-HT) which resulted in similar treatment effectiveness compared to the TCAs, with decreased side effect profiles in all of the SSRIs besides zimelidine. Zimelidine was the first SSRI to be developed, but its production was discontinued due to its toxicity. Fluoxetine, the first SSRI to be marketed that is still in use, was first marketed by Eli Lilly and Co. in 1987. Another antidepressant medication first marketed in the 1980s is bupropion, an antidepressant with the brand name Wellbutrin which is not a serotonin reuptake inhibitor (SRI) but instead may facilitate dopamine (DA) neurotransmission and may affect norepinephrine (NE).

Development of the third-generation antidepressants began with the goal of obtaining compounds which expand upon the functionality of the SSRIs to include other pharmacological effects thought to affect depressive symptoms while maintaining low side effect profiles. The development of SNRIs as antidepressants followed the development of SSRIs starting in the 1980s, although testing for the appropriate approval for clinical use for the first SNRI marketed was not completed until 1993.

Nefazodone is a third-generation antidepressant first marketed in the United States in 1994 which inhibits the reuptake of 5-HT and NE, as well as acting as an antagonist at the 5-HT_{2A} and α_1 -adrenergic receptors. Another third-generation antidepressant, mirtazapine, was first marketed in the United States in 1996 and inhibits the reuptake of 5-HT and NE, as well as acting as a noradrenergic α_2 -autoreceptor blocker and a 5-HT₂ and 5-HT₃ antagonist.

Current Knowledge

Research has suggested that 5-HT, NE, and DA are involved in the pathophysiology of depression. Each of the antidepressants developed to date affects one to all three of these neurotransmitters in the central nervous system (CNS). Although many different antidepressant drugs and families of antidepressant drugs with different functionalities exist, including the SSRIs, SNRIs, TCAs, and MAOIs, currently these drugs do not differ much from one another in efficacy. However, different individuals may have a greater treatment response to one antidepressant medication than to another. Family history of clinical response to a specific antidepressant medication may be a predictor for the response of an individual to that drug in some cases.

The SSRIs are a commonly prescribed group of antidepressant medications which relieve symptoms of depression by selectively blocking the reuptake of 5-HT. This action of SSRIs in the CNS causes an increase in the amount of synaptic 5-HT. Before the neurons are desensitized to drug, this increase in synaptic 5-HT is counteracted by the stimulation of the presynaptic 5-HT_{1A} autoreceptor which inhibits the further release of 5-HT into the synapse. After about 10–14 days of drug treatment, this autoreceptor is desensitized, and the amount of synaptic 5-HT increases. The five SSRIs currently FDA-approved to treat major depressive disorder (MDD) and marketed in the United States are fluoxetine, sertraline, paroxetine, citalopram, and escitalopram. Fluoxetine, with the brand names Prozac and Sarafem, is also marketed for the treatment of obsessive-

compulsive disorder (OCD). Sertraline, with the brand name Zoloft, is also marketed for the treatment of OCD, panic disorder, posttraumatic stress disorder (PTSD), premenstrual dysphoric disorder (PMDD), and social anxiety disorder. Paroxetine, with the brand names Paxil, Paxil CR, and Pexeva, is also marketed for the treatment of OCD, panic disorder, social anxiety disorder, generalized anxiety disorder (GAD), and PTSD. Citalopram, with the brand name Celexa, is only marketed for the treatment of MDD. Escitalopram, with the brand name Lexapro, is also marketed for the treatment of GAD. Additionally, fluvoxamine, with the brand names Luvox and Luvox CR, although only marketed for the treatment of OCD in the United States, is often prescribed for the treatment of depression.

The SNRIs relieve symptoms of depression by blocking the reuptake of 5-HT and NE. These drugs are similar in clinical use to the SSRIs, but two have the additional effects of treating pain and physical symptoms, such as those of fibromyalgia (FM). The three SNRIs currently marketed in the United States for the treatment of depression are duloxetine, venlafaxine, and desvenlafaxine. Duloxetine, with the brand name Cymbalta, is also marketed for the treatment of GAD, diabetic peripheral neuropathy, FM, and chronic musculoskeletal pain. Venlafaxine, with the brand names Effexor and Effexor XR, is also marketed for the treatment of GAD, social anxiety disorder, and panic disorder. Desvenlafaxine, with the brand name Pristiq, is only marketed for the treatment of MDD. Additionally, milnacipran, with the brand name Savella, is marketed for the treatment of MDD in Japan, although it is only marketed for the treatment of FM in the United States.

Other antidepressants with different mechanisms of action than the SSRIs and SNRIs are bupropion, nefazodone, and mirtazapine. Bupropion, with the brand name Wellbutrin, is not an SRI but instead may potentiate DA activity and may affect NE. Nefazodone inhibits the reuptake of 5-HT and NE, as well as acting as an antagonist at the 5-HT_{2A} and α_1 -adrenergic receptors. Mirtazapine, with the brand names Remeron and Remeron SolTab, inhibits the reuptake of

5-HT and NE, as well as acting as a noradrenergic α_2 -autoreceptor blocker and a 5-HT₂ and 5-HT₃ antagonist.

The TCAs are a family of compounds which affect 5-HT and NE, as well as acting as anticholinergic or antimuscarinic agents, α -adrenergic antagonists, and antihistamines. Although these drugs seem to have similar efficacy to the SSRIs and SNRIs and may be more effective than those drugs, the TCAs are not as well tolerated and have more side effects than the SSRIs and the SNRIs. Clinically, the TCAs are rarely used due to their side effects. Although these compounds are named for their chemical rings, their side chains are believed to be more important to their functions. The TCAs with tertiary amine groups on their side chains tend not to be tolerated as well as the TCAs with secondary amine groups on their side chains. The TCAs with tertiary amine groups block the reuptake of 5-HT more strongly than they do NE, whereas the TCAs with secondary amine groups block the reuptake of NE more strongly than they do 5-HT. The nine TCAs currently marketed for the treatment of depression in the United States are doxepin, trimipramine, amoxapine, maprotiline, imipramine, amitriptyline, nortriptyline, protriptyline, and desipramine.

Doxepin, marketed under the brand name Sinequan, is labeled for use as a treatment for psychoneurotic individuals, alcoholic individuals, and individuals with an organic disease with comorbid depression, anxiety, or both, and for individuals with psychotic depressive disorders with anxiety. A formulation of doxepin is also marketed with the brand name Silenor to treat insomnia, and a cream with doxepin hydrochloride as its active ingredient is marketed with the brand name Zonalon for the short-term treatment of pruritus in adults with atopic dermatitis or lichen simplex chronicus. Trimipramine, with the brand name Surmontil; amoxapine, formerly with the brand name Asendin; maprotiline, with the brand name Ludiomil; imipramine, with the brand name Tofranil; a formulation combining amitriptyline hydrochloride with perphenazine, with the brand names Triavil 2–10, Triavil 2–25, Triavil 4–10, Triavil 4–25, and Triavil 4–50;

nortriptyline, with the brand name Pamelor; protriptyline, with the brand name Vivactil; and desipramine, with the brand name Norpramin, are marketed only for the treatment of depression. Additionally, a formulation combining amitriptyline hydrochloride with chlordiazepoxide, with the brand name Limbitrol, is marketed as a treatment for depression associated with anxiety. In addition to these nine TCAs, clomipramine, with the brand name Anafranil, is marketed only for the treatment of OCD in the United States but is marketed for the treatment of MDD in Europe.

Many MAOIs exist for the treatment of various pathologies. MAOIs act by inhibiting monoamine oxidase (MAO) enzymes in the nervous system. Since MAO is located on the outer surface of mitochondria, it can only deaminate species in the cytoplasm and not species inside organelles, thereby keeping the concentration of amines in the cytoplasm low unless inhibited. The inhibition of the MAO enzymes by the MAOIs is not thought to be the direct cause of the alleviation of the symptoms of depression as has been observed from treatment with MAOIs. Secondary effects of these drugs are thought to be important for their use for the treatment of depression. The MAOIs are not widely used to treat depression due to their risks, including the risk of hypertensive crisis.

The four MAOIs currently marketed in the United States for the treatment of depression are phenelzine, isocarboxazid, tranylcypromine, and selegiline. Phenelzine, with the brand name Nardil, is marketed for the treatment of atypical, non-endogenous, or neurotic individuals with depression. Isocarboxazid, with the brand name Marplan, is marketed for the treatment of depression. Tranylcypromine, with the brand name Parnate, is marketed for the treatment of major depressive episodes without melancholia. Selegiline, with the brand name Emsam, is marketed for the treatment of MDD.

Important safety issues must be noted with the use of antidepressant medications. The use of antidepressants in children and adolescents may increase depressive symptoms or cause the onset of suicidal ideation; therefore, appropriate discretion must be used when prescribing SRIs in

children, adolescents, or young adults with depression. Also, the concomitant use of SRIs and MAOIs is a known cause of serotonin syndrome which is potentially lethal; therefore, these drugs should not be prescribed concomitantly, and time should be allowed between discontinuation of one of these types of drugs and the initiation of treatment with a drug of the other type. At least 2 weeks must be allowed before beginning an MAOI after discontinuing most SSRIs, although at least 5 weeks must be allowed before beginning an MAOI after discontinuing fluoxetine. At least a few days must be allowed before beginning an MAOI after discontinuing a TCA.

MAOIs have adverse drug interactions with various drugs including the SRIs, serotonin agonists, stimulants, direct sympathomimetics, indirect sympathomimetics, and antidiabetic agents. Also, MAOIs have adverse interaction with some foods which is thought to be due to increased tyramine levels. Important safety precautions must be taken during the use of MAOIs including the avoidance of certain foods: cheese, overripe fruit, fava beans, sausage, salami, sherry, liqueurs, sauerkraut, monosodium glutamate, pickled fish, brewer's yeast, beef liver, chicken liver, fermented products, and red wine. Additionally, the following foods should be used in moderation during the use of MAOIs: coffee, chocolate, colas, tea, soy sauce, beer, and wines other than those previously listed which should be avoided during the use of MAOIs.

Future Directions

In recent years, the development of new, more efficacious antidepressants has been attempted by combining the effects of SRIs with other pharmacological effects. Other antidepressant drugs similar to the third-generation antidepressants are being developed with novel mechanisms of action. For example, a group of compounds known as serotonin-norepinephrine-dopamine reuptake inhibitors (SNDRIs) are being developed for potential clinical use in the treatment of depressive disorders. At least five SNDRI compounds have been developed. Other

compounds being developed and investigated are SRIs and 5-HT_{2A} antagonists; at least 27 of these compounds have been developed to date. The treatment of depression with a combination of SRIs with atypical antipsychotics is another approach being investigated. Other compounds with SRI activity have reportedly been developed, but these compounds require further testing to determine their viability as medications.

Selective serotonin reuptake inhibitors (SSRIs);
Tricyclic antidepressants (TCAs)

Definition

Antidepressants are a broad group of medications with various mechanisms of action. Until the early 1990s, the most commonly used antidepressants were the so-called tricyclic antidepressants (TCAs). More recently, the most commonly used antidepressants are the selective serotonin

reuptake inhibitors (SSRIs). Other antidepressants include bupropion, serotonin and noradrenaline reuptake inhibitors (SNRIs), and more unique medications like mirtazapine. Medications that are typically used as mood stabilizers (such as lithium) or antipsychotics (such as aripiprazole) also have efficacy for treating depression although they are not typically classified as antidepressants.

SSRIs are a class of medications that includes fluoxetine, fluvoxamine, paroxetine, sertraline, citalopram, and escitalopram. As the name suggests, SSRIs block the reuptake of released serotonin at the presynaptic serotonin transporter. This action prolongs the presence of serotonin in the synapse, which is a major neurotransmitter in the brain.

Neurotransmitters are used to communicate messages from one nerve to the next nerve. Unlike conventional electrical wiring, which requires wire-to-wire contact to move the electrical signal onward, nerve endings do not make physical contact with one another. The transmitting nerve ending comes near, but does not touch, the neighboring nerve ending. The message is carried by a neurotransmitter such as serotonin, dopamine, norepinephrine, or acetylcholine.

Once the neurotransmitter, such as serotonin, is released to carry the message to the neighboring neuron, there is a series of regulatory steps designed to return the system to the resting state. Reuptake, which is an important regulatory mechanism, is an active process of recovering released neurotransmitter back into the transmitting nerve ending. If a drug blocks serotonin reuptake, it permits the neurotransmitter to remain in the synaptic space longer. Although this is a known effect of the SSRIs, there is often a delay between starting the medication and achievement of beneficial effects. This suggests that the blockade of serotonin reuptake, which occurs with the first dose of medication, is not a complete explanation for the therapeutic effect of these medications.

The tricyclic antidepressants (abbreviated TCAs) are an older class of antidepressants that include imipramine, desipramine, clomipramine, amitriptyline, and nortriptyline. The term tricyclic refers to the three-ring structure of this class of antidepressant medications. These medications are not used as commonly as in the past as they

have been largely replaced by the SSRIs. Imipramine has been used to treat both depression and anxiety. Desipramine has been used to treat depression and attention deficit hyperactivity disorder. Clomipramine is often considered a breakthrough because it was the first medication shown to be effective for the treatment of obsessive-compulsive disorder. These three compounds, imipramine, desipramine, and clomipramine, represent three distinct modes of action for drugs in the same class. For example, desipramine has highly selective norepinephrine reuptake inhibitor properties. By contrast, clomipramine is well known for its more selective serotonin reuptake inhibiting properties. Indeed, clomipramine served as a model for the next generation of selective serotonin reuptake inhibitors (see below). Imipramine is intermediate with both norepinephrine and serotonin reuptake inhibiting properties. Other members of the class, such as nortriptyline and protriptyline, are predominately norepinephrine reuptake inhibitors.

The tricyclic antidepressants have several adverse effects in common including dry mouth, urinary retention, constipation, nausea, increased heart rate, dizziness, and, at higher doses, confusion. The tricyclic antidepressants also carry some risk of altering the electrical conduction in the heart. They are well known to be fatal on overdose due to their potential for causing cardiac arrhythmia. Because of their known toxicity at higher doses, treatment with tricyclic antidepressants requires blood-level monitoring and electrocardiogram monitoring as well. Finally, the tricyclic antidepressants are also vulnerable to drug-drug interaction. For example, some medications such as SSRIs or certain antibiotics may interfere with the breakdown of tricyclic antidepressant medications. The interference of metabolism of the tricyclic can cause a sharp increase in the blood levels of the tricyclic antidepressants and increase the vulnerability to toxic effects. The tricyclic medications have not been well studied in children or adults with autism.

[Anticonvulsants](#); [Antiseizure medications](#)

Indications

The decision about which antiepileptic drug (AED) to use is based on both the seizure type and the epilepsy syndrome along with the efficacy and toxicity profile of the AEDs for the various

types of seizures. A list of the most common AEDs used in autism spectrum disorders is described below. Each drug is listed with the following categories: indications, mechanism of action/metabolism, adverse effects, and dosing.

Mechanisms of Action

Mechanisms of action (provided under each entry below)

Specific Compounds and Properties

Phenobarbital

Phenobarbital (PB) is classified as a barbiturate and displays a broad spectrum of anticonvulsant activity. It was first introduced in 1912. It remains the oldest anticonvulsant commonly used and the most widely used around the world.

Indications: Phenobarbital is effective for generalized tonic-clonic seizures as well as partial seizures. PB is also effective for status epilepticus. It is usually the drug of choice for neonatal seizures. It is not effective for absence seizures.

Mechanism of action/metabolism: PB works by enhancing gamma-aminobutyric acid (GABA) inhibition. It is extensively metabolized in the liver. PB undergoes autoinduction whereby clearance may be increased requiring increasing dose adjustment when used as monotherapy.

Adverse effects: The most common adverse effect is sedation; however, tolerance to sedation usually develops with continued use of the drug. Other common side effects include irritability, hyperactivity, ataxia, and cognitive impairment. Decreased bone mineral density may occur. Rash occurs as an idiosyncratic reaction with very rare occurrence of Stevens-Johnson syndrome and toxic epidermal necrolysis. Other rare adverse effects include megaloblastic anemia and respiratory depression. Weight change is not common.

Dosing: PB is available in the following formulations: liquid (20 mg/5 ml), tablets (15 mg, 30 mg, 60 mg, 100 mg). Intravenous preparation is available. Average daily dosing is in the range of 4–11 mg/kg/day in children less than 1 year, 2–7 mg/kg/day for children over 1 year, and

1.5–4 mg/kg/day for children over age 12 and adults. Loading doses are effective ways of rapidly achieving a therapeutic level. PB should be gradually tapered after chronic use to avoid withdrawal seizures, usually over 3–6 months.

Phenytoin (Dilantin)

Phenytoin (PHT) was introduced in 1938 as being useful in controlling seizures without sedative effects as seen in phenobarbital. In addition to its use as an antiepileptic drug, it is also used in treatment of trigeminal neuralgia.

Indications: Phenytoin is effective for partial seizures as well as generalized tonic-clonic seizures. PHT is also highly effective for status epilepticus. It is useful in the treatment of neonatal seizures. It is not effective for absence and myoclonic seizures.

Mechanism of action/metabolism: PHT acts as a use-dependent blocker of voltage-sensitive sodium channels. It inhibits calcium channels and calcium sequestration. PHT is extensively metabolized in the liver. It undergoes autoinduction whereby clearance may be increased requiring increasing dose adjustment when used as monotherapy.

Adverse effects: Common adverse effects are cosmetic including acne, gingival hyperplasia, and hirsutism. Nausea, vomiting, nystagmus, vertigo, ataxia, and lethargy may occur with toxicity. Rare adverse effects include hyperglycemia, movement disorders, and confusional states. More serious side effects include rare hepatotoxicity and hematological abnormalities, including thrombocytopenia, anemia, leukopenia, and agranulocytosis. Other rare life-threatening effects include lymphadenopathy and serious rash including Stevens-Johnson syndrome and toxic epidermal necrolysis. Effect on weight is not common.

Dosing: PHT is available in the following formulations: chewable tablets (50 mg), capsules (30 mg, 100 mg). An oral suspension is available but discouraged from use as it is unstable. Intravenous preparation is available. Average daily dosing is in the range of 4–10 mg/kg/day for children and 300–400 mg/day for adults. Neonates may require more than 10 mg/kg/day.

As with most AEDs, discontinuation should be done with gradual dose reduction over several weeks, unless there is concern for serious adverse effect.

Carbamazepine (Tegretol)

Carbamazepine (CBZ) was initially marketed in 1962 for the treatment of trigeminal neuralgia and shortly after for the treatment of epilepsy. It is particularly effective in the treatment of focal epilepsies. In addition to its use as an anticonvulsant, it is beneficial for neuropathic pain and affective disorders including bipolar disorder.

Indications: Carbamazepine is effective in simple and complex partial seizures as well as generalized tonic-clonic seizures. It is not indicated for use in neonatal or febrile seizures. It is contraindicated in the treatment of generalized seizures seen in idiopathic generalized epilepsy, as well as absence seizures. It is not used in the treatment of epileptic encephalopathies.

Mechanism of action/metabolism: Carbamazepine acts as a use-dependent blocker of voltage-sensitive sodium channels. It inhibits the release of glutamate. CBZ is extensively metabolized in the liver. Carbamazepine exhibits autoinduction whereby clearance may be increased requiring increased dose adjustment when used as monotherapy.

Adverse effects: Common adverse effects include gastrointestinal distress, drowsiness, confusion, headaches, dizziness, ataxia, and blurred or double vision. Aplastic anemia, agranulocytosis, and liver toxicity are rare but nonetheless serious potential reactions that can occur with carbamazepine use. Therefore, hematologic and hepatic parameters should be monitored, especially in the first 6 months of therapy. Rare occurrence of severe rash, including Stevens-Johnson syndrome, and cardiac arrhythmias has been seen. CBZ may cause syndrome of inappropriate antidiuretic hormone (SIADH) with hyponatremia since it both increases the release and potentiates the action of ADH (vasopressin). Weight change is not typical.

Dosing: CBZ is available in the following formulations: liquid (100 mg/5 mL), chewable tablets (100 mg), tablets (200 mg), extended release

sprinkle capsule (Carbatrol) in 100 mg, 200 mg, 300 mg, and extended release tablets (Tegretol-XR) in 100 mg, 200 mg, 400 mg. Average daily dosing is in the range of 10–30 mg/kg/day for children and 600–1,200 mg/day for adults.

Valproic Acid (Depakote)

Valproic acid (VPA) is often referred to as valproate. Its anticonvulsant properties were first discovered in the early 1960's and since then has become one of the most commonly prescribed anticonvulsants worldwide. It is a broad-spectrum AED, effective against all types of seizures and epilepsies. In addition to its use as an AED, it is also used frequently for migraine prophylaxis and treatment of manic episodes of bipolar disorder.

Indications: VPA is highly effective in treatment of generalized epilepsies. It is effective for all types of generalized seizures including myoclonic and absence seizures. It is also used in the treatment of partial seizures. Febrile seizures, refractory status epilepticus, and epileptic encephalopathies, including Lennox-Gastaut syndrome, may be treated with VPA.

Mechanism of action/metabolism: The primary mechanism of action of VPA is not clear but may act by any one of the following: increasing levels of GABA by decreasing its metabolism, blocking voltage-gated sodium channels and T-type calcium channels, or decreasing levels of excitatory amino acid aspartate. VPA is extensively metabolized in the liver.

Adverse effects: Common adverse effects include mild sedation, nausea, vomiting, and anorexia. These side effects commonly occur during initiation of therapy and are usually transient. Alopecia and tremor may occur, but effects on cognition are minimal. The major serious adverse side effects relate to hepatic dysfunction. Fatal hepatotoxicity is considered to be an idiosyncratic reaction rather than a dose-related phenomenon. Children younger than 2 years old are at higher risk. Therefore, serum transaminases (AST, ALT) should be obtained prior to initiation of therapy and periodically during treatment. Thrombocytopenia more than leukopenia can occur and appears to be a dose-related phenomenon. Routine monitoring of CBC and platelets is usually

recommended. Fatal pancreatitis has been reported, albeit rare. If clinically indicated, serum amylase and lipase should be obtained. Hyperammonemia may occur and is often asymptomatic. Usual treatment is L-carnitine but exclusion of urea cycle disorders may be warranted. VPA should not be used in patients with suspected mitochondrial disorders. Weight gain is common.

Dosing: VPA is available in the following formulations: liquid (250 mg/5 mL), sprinkle capsules (125 mg), tablets (125 mg, 250 mg, 500 mg), and extended release tablet (250 mg, 500 mg). It is also available intravenously. Average daily doses are 30–60 mg/kg/day in children and 1,000–3,000 mg/day in adults. L-carnitine supplementation is suggested in certain individuals, especially in young children. As with most AEDs, discontinuation should be done with gradual dose reduction over several weeks, unless concern for serious adverse effect.

Oxcarbazepine (Trileptal)

Oxcarbazepine (OXC) is an analogue of carbamazepine (CBZ) with a keto group at the ten carbon position. It is rapidly metabolized to a 10-monohydroxy metabolite, which is primarily responsible for its anticonvulsant effects. Its anticonvulsant profile is nearly identical to CBZ, but it is better tolerated.

Indications: Oxcarbazepine is similar to carbamazepine in its antiepileptic efficacy. It is effective for simple and complex partial seizures as well as generalized tonic-clonic seizures. It may be particularly useful in individuals who do not tolerate CBZ but respond to CBZ. It is not indicated for use in neonatal or febrile seizures. It is contraindicated in the treatment of generalized seizures seen in idiopathic generalized epilepsy, as well as absence seizures. It is not used in the treatment of epileptic encephalopathies.

Mechanism of action/metabolism: Oxcarbazepine acts a use-dependent blocker of voltage-sensitive sodium channels. It inhibits the release of glutamate. Oxcarbazepine is rapidly metabolized in the liver to 10-hydroxycarbazepine, its pharmacologically active metabolite. Compared with CBZ, OXC has less prominent actions on CYP

450 enzyme systems and therefore, fewer pharmacokinetic interactions. It does not exhibit auto-induction, binds less to serum proteins, has fewer drug interactions, and thus, a lower incidence of side effects than CBZ.

Adverse effects: Common adverse effects include somnolence, headache, dizziness, blurred/double vision, nausea, and vomiting. There is risk of rash, including Stevens-Johnson syndrome and toxic epidermal necrolysis, but the risk is lower with OXC as compared with CBZ. There is a 25–30% incidence of cross-reactive rash with CBZ. As with CBZ, hyponatremia may occur. Hematologic effects, including agranulocytosis and aplastic anemia, are very rare. Hepatotoxicity is not a side effect, as in CBZ. Weight gain is not common.

Dosing: OXC is available in the following formulations: liquid (300 mg/5 mL), tablets (150 mg, 300 mg, 600 mg). Average daily doses are 600–1,200 mg/day for children less than 30 kg and 900–1,800 mg/day for children 30–60 kg. Average doses for adults are 600–2,400 mg/day.

Lamotrigine (Lamictal)

Lamotrigine (LTG) is a broad-spectrum antiepileptic drug that is used for all seizure types with the exception of epilepsies with prominent myoclonic jerks. In addition to its use as an AED, it is also used for treatment of bipolar disorder, migraines, and other headaches, along with trigeminal neuralgia and other neuropathic pain disorders.

Indications: Lamotrigine is effective for the treatment of both partial and generalized seizures, including absence seizures. It is also used in treating Lennox-Gastaut syndrome.

Mechanism of action/metabolism: Lamotrigine acts a use-dependent blocker of voltage-sensitive sodium channels. It inhibits the release of the excitatory amino acid, glutamate. LTG is extensively metabolized in the liver.

Adverse effects: Common adverse effects include rash. Nonspecific rashes occur in approximately 10% of patients and the vast majority of these are benign. However, rare cases of Stevens-Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN) have been reported. The

incidence of SJS and TEN is higher in individuals younger than 16 years of age. Concurrent use of valproic acid and rapid escalation of LTG doses are both thought to be risk factors for the development of these rashes. The risk of rash is thought to be higher in the first 6–8 weeks of therapy. However, SJS has developed in LTG monotherapy and after several months of therapy. Other common risks include headache, nausea, vomiting, diplopia, ataxia, and insomnia, especially when combined with carbamazepine. Hematologic and hepatic effects are rare. Weight gain is not common.

Dosing: LTG is available in the following formulations: chewable tablets (2 mg, 5 mg, 25 mg), orally disintegrating tablets (25 mg, 50 mg, 100 mg, 200 mg), tablets (25 mg, 100 mg, 150 mg, 200 mg), and extended release tablets (25 mg, 50 mg, 100 mg, 200 mg). Average daily doses vary depending on whether LTG is used as monotherapy or with Valproic Acid (VPA) or other enzyme-inducing AEDs. Enzyme-inhibiting drugs such as VPA increase LTG levels, whereas enzyme-inducing drugs such as PB, PHT, and CBZ decrease LTG levels. Therefore, initial and maintenance doses need to be adjusted accordingly. Slow dosage titration is recommended to reduce the risk of potential severe reactions, especially skin rash.

Levetiracetam (Keppra)

Levetiracetam is a broad-spectrum antiepileptic drug. It is widely used due to its low propensity for drug interactions, relatively benign side-effect profile, and effectiveness for nearly all types of epilepsies. It is also used for treatment of neuropathic or chronic pain.

Indications: Keppra is effective in the treatment of both partial and generalized seizures. It is not contraindicated for any seizure type, although experience in neonates and use for febrile seizures is limited. It is used in treatment of status epilepticus.

Mechanism of action/metabolism: The precise mechanism of action of levetiracetam has not yet been established. Levetiracetam is not metabolized in the liver, and thus, its metabolism does not depend on the hepatic cytochrome P450

enzymes. Therefore, doses do not need to be adjusted in those with hepatic impairment.

Adverse effects: Common adverse effects include somnolence, ataxia, and dizziness. Behavioral symptoms including irritability, agitation, aggression, emotional lability, anxiety, and depression may occur and are thought to be more common in children than adults. These symptoms are more common at initiation of the drug and often subside within the first few months of use. Use of pyridoxine (vitamin B6) has been suggested to decrease the occurrence of behavioral side effects, but this has not been proven in controlled data. Behavioral symptoms that persist often require discontinuation of the drug. Levetiracetam has no organ toxicity, and therefore, serious or life-threatening side effects are exceedingly rare. Weight gain is not common.

Dosing: Levetiracetam is available in the following formulations: 100 mg/ml (liquid), tablets (250 mg, 500 mg, 750 mg, 1,000 mg), and extended release tablets (500 mg). Intravenous solution is available. Average daily doses range between 30 and 60 mg/kg/day for children and 1,000–3,000 mg/day for adults.

Zonisamide (Zonegran)

Zonisamide is a broad-spectrum antiepileptic drug. It is not contraindicated for any particular type of epilepsy. In addition to its use as an anti-convulsant, it is used in treatment of migraines, obesity, and bipolar disorder.

Indications: Zonisamide is effective in the treatment of both partial and generalized seizures. It is the drug of choice for myoclonic seizures. It is useful in the management of epileptic encephalopathies along with Lennox-Gastaut syndrome and infantile spasms.

Mechanism of action/metabolism: The exact mechanism of action is not known. Although it may be a carbonic anhydrase inhibitor, this is not how it exerts its antiepileptic effects. It seems to block sodium and T-type calcium channels along with inhibiting the uptake of GABA and enhancing the uptake of glutamate.

Adverse effects: Common adverse effects include drowsiness, dizziness, ataxia, fatigue, nausea, vomiting, decreased appetite, and headache.

Metabolic acidosis, hypohidrosis, and cognitive/behavioral changes occur more commonly in children. Paresthesias and kidney stones are reported but uncommon. Life-threatening side effects such as Stevens-Johnson syndrome, blood dyscrasias, and hyperthermia are extremely rare. Use with caution when combining with other carbonic anhydrase inhibitors or anticholinergics due to risk for hypohidrosis and resultant hyperthermia. Weight loss is common.

Dosing: ZNM is available in the following formulations: capsules (25 mg, 50 mg, 100 mg). Average daily dosing for monotherapy in children is 8 mg/kg/day and 12 mg/kg/day when used with enzyme-inducing AEDs. Average daily doses range between 100–400 mg/day for adults.

Vigabatrin

Vigabatrin (VGB) is primarily used in the treatment of infantile spasms but is also effective in partial epilepsies. Due to its serious potential effects on vision, it had not been approved for use in the United States until 2009. It is now available for use as monotherapy for children ages 1 month to 2 years with infantile spasms and adjunctive therapy for adults with refractory complex partial seizures in whom the potential benefits outweigh the risks for vision loss.

Indications: Vigabatrin is effective against infantile spasms, especially if spasms are due to tuberous sclerosis. It is also used in the treatment of partial seizures. It is contraindicated in absence seizures and may provoke absence status epilepticus.

Mechanism of action/metabolism: Vigabatrin irreversibly inhibits GABA transaminase, the enzyme that breaks down GABA, effectively increasing GABA levels. Vigabatrin is not metabolized in the liver.

Adverse effects: The potential for visual field defects may be idiosyncratic, but dose- and duration-dependent toxicity has been reported. It has been reported in approximately 30% of patients. The onset usually occurs between 6 months and 2 years but is not typically reversible. Therefore, treatment with vigabatrin should not be continued if there is no response to treatment within 3 months. Other common adverse effects include somnolence, dizziness, headache,

and ataxia. Behavioral, mood, and cognitive changes are also reported. Life-threatening side effects are rare, including encephalopathic syndromes. Angioedema, hallucinations, and rash are rare. Weight gain is common.

Dosing: Vigabatrin is available in the following formulations: sachet, i.e., powder (500 mg), tablets (500 mg). Average daily doses for infants with infantile spasms are 100–200 mg/kg/day. Average doses for children are 2,000–3,000 mg/day and 1,000–3,000 mg/day for adults.

Topiramate (Topamax)

Topiramate (TPX) is a broad-spectrum antiepileptic drug that is used for all seizure types. In addition to its use as an AED, it is commonly used for migraine prophylaxis. It is also used in treatment of bipolar disorder and obesity.

Indications: Topiramate is effective for both partial and generalized seizures. It is also used in the treatment of infantile spasms, Lennox-Gastaut syndrome, and progressive and idiopathic myoclonic epilepsies. It is not contraindicated for any type of seizures.

Mechanism of action/metabolism: The exact mechanism of action is not known, but TPX appears to act by inhibiting voltage-dependent sodium channels, enhancing GABA-mediated inhibition, and decreasing glutamate-mediated excitatory neurotransmission. It also inhibits carbonic anhydrase, but this is not how it exerts its antiepileptic effects. It is metabolized in the liver, especially when used with enzyme-inducing AEDs.

Adverse effects: Common adverse effects include somnolence, mental slowing, impaired concentration or confusion, and word-finding difficulties. Paresthesias occur frequently with monotherapy, more frequently in adults than children. Other side effects include dizziness, weight loss, metabolic acidosis, and hypohidrosis. Rare side effects include nephrolithiasis and glaucoma. Serious side effects are related to metabolic acidosis and oligohidrosis that leads to hyperthermia. The risk of these is higher in children than in adults. Hepatotoxicity and bone marrow depression do not occur. Weight loss is common.

Dosing: TPX is available in the following formulations: sprinkle capsules (15 mg, 25 mg) and

tablets (25 mg, 50 mg, 100 mg, 200 mg). Average daily doses for children are 5–10 mg/kg/day and 200–400 mg/day for adults.

Benzodiazepines

Benzodiazepines have been used especially for the treatment of status epilepticus and repetitive or cluster seizures. They are commonly used as adjunctive agents or as temporary drugs while waiting to achieve therapeutic concentrations of mainstay therapy. Diazepam, lorazepam, and midazolam are used for status epilepticus while clobazepam, clonazepam, and clobazam are used for chronic anticonvulsant therapy. Clobazam is not available in the USA.

Major side effects include sedation, ataxia, and behavioral problems such as hyperactivity, irritability, moodiness, restlessness, and aggression. Disinhibition is common. Tolerance to benzodiazepines occurs frequently.

Diastat is the rectal gel preparation of diazepam that has been approved for use with acute repetitive seizures and cluster seizures. Although not approved for use in status epilepticus, it is used for treatment of prolonged seizures at home. It is usually recommended for seizures lasting greater than 5 min in duration. This is very useful as it allows caregivers to intervene early on and potentially avoid the need for emergency room care. It is supplied in doses of 2.5 mg, 5 mg, 10 mg, 15 mg, and 20 mg that is dosed by weight (0.5–0.3 mg/kg). Serious side effects are rare, including respiratory depression.

ACTH and Steroids

ACTH (adrenocorticotrophic hormone) is used in the treatment of infantile spasms. It is also used in other epileptic encephalopathies, such as Lennox-Gastaut syndrome, Landau-Kleffner syndrome, and Dravet syndrome. As such, ACTH is used almost exclusively in children.

Steroids, especially prednisone, have been used to treat acquired epileptic aphasia of childhood (Landau-Kleffner syndrome) and electrical status epilepticus of sleep (ESES). In these disorders, oral prednisone is most commonly used.

Common side effects include irritability, weight gain, hypertension, and hyperglycemia. Serious side effects include peptic ulcers, cataracts/

glaucoma, cardiomyopathy, and brain atrophy. Life-threatening adverse effects include immunosuppression, sepsis, and congestive heart failure.

Clinical Use (Including Side Effects)

AEDs are commonly administered to children and adolescents with ASD, both with and without epilepsy. Two of the most widely used AEDs in the ASD population include valproic acid and lamotrigine. As described herein, many AEDs have a psychotropic effect and are used in treating psychiatric symptoms and disorders, such as bipolar disorder, obsessive-compulsive disorder, mood lability, irritability, and aggressive behaviors. As many children with ASD have coexisting affective disorders, AEDs are an attractive drug of choice for targeting both mood disturbances as well as epilepsy. There are reports of behavioral improvements for children with ASD and epileptiform EEG abnormalities without clinical seizures; however, at present time, there are no data to support the use of antiepileptic drugs in the treatment of these abnormalities in the absence of clinical seizures. Whether these AEDs have a positive psychotropic effect on children with ASD, with and without epilepsy, is not currently known. There is a need for large randomized control trials in this area in order to determine the efficacy of these AEDs in treating the core symptoms of autism.

Antigluten Therapy

Madison Pilato
Neurodevelopmental and Behavioral Pediatrics,
University of Rochester Medical Center,
Rochester, NY, USA

Definition

Antigluten therapy is the elimination of gluten from the body by dieting and/or supplemental enzymes. This entry will examine enzyme supplements that break down gluten. (For elimination diets, see ► [“Gluten-Free Diet”](#).)

Historical Background

In 1979, Jaak Panksepp hypothesized that the symptoms of autism may be caused by an opiate excess, although he was unsure how such an excess might come about. Starting in the 1980s, some investigators reported abnormal peptide concentrations in the urine of children with autism and proposed that enzyme deficiencies caused this abnormality (Trygstad et al. 1980; Reichelt et al. 1981, 1990). Additionally, these investigators speculated that the abnormal peptide concentrations reflected abnormal levels of opioid peptides in the brain (Trygstad et al. 1980; Reichelt et al. 1981). More recently, Andrew Wakefield (Wakefield et al. 1998) described intestinal abnormalities in several children with autism and hypothesized that this abnormality could provide another explanation for the opiate-excess theory. More specifically, he hypothesized that

children with autism have a leaky gut that results in the release of opioids that enter blood vessels and circulate into the brain. However, Wakefield's study has since been retracted by The Lancet and is considered to be unreliable.

Rationale or Underlying Theory

Antigluten therapy is based on the opioid-excess, enzyme deficiency, and leaky gut theories. According to the opioid-excess theory, the core symptoms of autism may be explained by disrupted opiate activity in the brain (Panksepp 1979). One proposed explanation for this theory is that children with autism have deficient peptidase enzymes (Trygstad et al. 1980; Reichelt et al. 1981). However, Hunter et al. (2003) did not find dipeptidyl peptidase IV to be defective in children with autism. A “leaky gut” or increased intestinal permeability has also been theorized to cause an opioid excess and to be associated with autism. The theory suggests that undigested proteins and peptides leak into the bloodstream through the intestines, eventually causing damage and/or disrupted opioid receptor activity in the brain. However, this theory lacks empirical support as it is based on a discredited study (Wakefield et al. 1998) that found intestinal abnormalities in several children with autism and that has not been replicated by other investigators (Buie et al. 2010; Fernell et al. 2007; Sandhu et al. 2009).

Another uncorroborated theory that has been adduced to support antigluten therapy is that children with autism have a wheat allergy and other symptoms similar to celiac disease (Lucarelli et al. 1995). However, there is no evidence for increased co-occurrence of wheat allergies or celiac disease and autism spectrum disorders (Fitzgerald et al. 1999; McCarthy and Coleman 1979).

Goals and Objectives

The goals of antigluten therapy include administering digestive enzymes to assist in the breakdown of gluten and preventing undigested gluten and gluten derivatives from affecting the body.

Efficacy Information

For information on the efficacy of gluten-free diets, see ► [“Gluten-Free Diet”](#).

To date, there are only two empirical studies examining the efficacy of enzyme supplements to break down gluten for individuals with autism. Brudnack et al. (2002) placed 46 patients on a combination of several enzymes for 12 weeks. Several behavioral parameters were measured every 2 weeks for the entire 12 weeks. The authors report improvement on every measure including core symptoms. However, there was no control group, the baseline measures were assumed to be zero rather than measured directly, and behavioral evaluators were aware that the children had received a supplement. Additionally, behavioral measurements were collected from an “SOS” form (not shown or explained in the manuscript) in addition to scoring by an observer, and it is not clear whether the observer was distinct from a teacher, parent, or guardian who completed the SOS form. No standardized instruments (i.e., ADOS, Vineland, Mullen, etc.) were used. Despite the reported improvements, the numerous methodological weaknesses in the study make the results unreliable.

Munasinghe et al. (2010) conducted a more scientifically rigorous study that incorporated a randomized, double-blind, crossover design. Only food selection improved significantly at the month 2 measurements. Improvements were not sustained at 3 months. Thus, the two available studies provide insufficient information to recommend antigluten therapy in the form of enzymatic supplements at this time.

Outcome Measurement

Antigluten treatment is intended to reduce autism symptoms and improve adaptive functioning. Therefore, if clinical trials of antigluten therapy are undertaken, outcome measures should include measures of autism symptoms such as the ADOS and measures of adaptive behavior such as the Vineland. Also, because digestive enzymes are administered, measures of nutrition and vital signs should be included.

Qualifications of Treatment Providers

Caregivers should consult a board-certified physician before beginning antigluten therapy. Additionally, the use of enzyme supplements should be supervised by a physician.

Anti-Hist [OTC]

► Diphenhydramine

Antihistamines: Definition

Karthikeyan Ardhanareeswaran
Autism Program, Child Study Center, Yale School of Medicine, New Haven, CT, USA
Program in Neurodevelopment and Regeneration, Yale School of Medicine, New Haven, CT, USA
Department of Molecular, Cellular, and Developmental Biology, Yale University, New Haven, CT, USA

Synonyms

H₁ receptor antagonist; H₁ receptor inverse agonist

Definition

Antihistamines are a class of drugs that inhibit histamine, a neurotransmitter involved in mood and behavior regulation, by either (a) blocking

the action of histamine at the receptor, (b) competing with histamine for binding to the receptor, or (c) displacing histamine from the receptor. In the field of ASD, the majority of interest surrounds mirtazapine and cyproheptadine, both nonselective H₁ receptor (histamine receptor) inverse agonists (similar to antagonist). Mirtazapine specifically shows promise in treating inappropriate sexual behaviors associated with autism. However, the mechanism of action of both these drugs in the context of ASD is likely to be through antihistamines' off-target highly potent antagonism of α -adrenergic receptors (fight-or-flight response) and/or serotonin (mood regulation) receptors as opposed to the H₁ receptor. Antihistamines may be useful in the treatment of sleeping problems associated with autism; however, evidence suggests a greater effectiveness in this regard in typically developing children.

Histamine's more prominent role is as an inflammation mediator, increasing permeability of blood vessels to immune cells. In concordance, antihistamines are normally used in the treatment of allergies by blocking histamine-induced vasodilation and swelling. Common side effects include dry mouth, drowsiness, dizziness, nausea, and vomiting.

Antipsychotic-Induced Dyskinesia

► Tardive Dyskinesia

Antipsychotics: Drugs

Susan Boorin
School of Nursing, Yale University, West Haven,
CT, USA

Synonyms

Neuroleptics

Indications

Schizophrenia, bipolar mood disorder, significant irritability, and aggression

Mechanisms of Action

There has been considerable debate about the difference between the traditional antipsychotics and the so-called atypicals. Indeed, the matter is not completely settled. It is generally agreed that the traditional antipsychotics exert their beneficial and adverse effects through dopamine blockade at the dopamine D2 receptor. The traditional antipsychotic, haloperidol, is a potent blocker of dopamine. Its capacity to bind to D2 receptors is strong, and it is not easily displaced by dopamine in the brain. This affinity and persistent binding to D2 receptors in the basal ganglia probably

accounts for the motor side effects described above. By contrast, clozapine (often considered the prototype atypical) has much lower affinity for D2 receptors. Across the current list of atypical antipsychotics, the affinity for D2 receptors varies. For example, risperidone has strong affinity for D2 receptors – but it does not appear to have the same firm hold on these receptors as haloperidol does. Because the hold on the D2 receptors is not firm, endogenous dopamine is more able to bind to the receptors, and we are less likely to see the motor side effects associated with haloperidol.

Specific Compounds and Properties

Antipsychotics

Antipsychotic medications are a large group of medications developed primarily for the treatment of schizophrenia. The antipsychotic medications were introduced in the 1950s with so-called second-generation antipsychotics appearing in the 1990s. These newer medications have properties in common with the older antipsychotics but also important differences.

Atypical Antipsychotics

Because of the adverse neurological effects of the traditional antipsychotic medications, chemists looked for new compounds that would maintain the antipsychotic benefits with decreased risk of neurological side effects. This led to the introduction of the so-called atypical antipsychotics. These medications include clozapine, risperidone, olanzapine, quetiapine, ziprasidone, aripiprazole, asenapine, iloperidone, and lurasidone. As a class, these atypical antipsychotics, also called second-generation antipsychotics, do indeed reduce the risk of neurological adverse effects. However, depending on the actual drug discussed, they have varying degrees of risk for other adverse effects.

Antiyeast Therapy

Madison Pilato
Neurodevelopmental and Behavioral Pediatrics,
University of Rochester Medical Center,
Rochester, NY, USA

Definition

Antiyeast therapy includes diets that restrict intake of sugar and yeast as well as supplements and drugs to eliminate yeast from the body.

Historical Background

Candida albicans is a form of yeast and is known to cause human infections. In works published from 1978 to 1981, C. Orian Truss was the first to propose the idea that the natural yeasts in the gastrointestinal tract can cause a variety of symptoms (Edwards 1988). In 1983, William Crook popularized this idea with his book, *The Yeast Connection*, in which he coined the term “Candida syndrome” to explain a host of psychological and neurological syndromes, including learning disabilities. He offered anecdotes as evidence for this syndrome, notably an account of “Candida drunken syndrome” that involved a boy with autism who was said to improve after antiyeast

interventions. The popularity of antiyeast therapies for the treatment of autism increased after Shaw et al. (1995) reported abnormal metabolites in the urine of two brothers with autism.

Rationale or Underlying Theory

Current antiyeast therapy was developed by Shaw et al. (1995) based on a report of abnormally high levels of metabolites in the urine of two siblings with autism, compared to typically developing children. These metabolites included citramalic acid, a citric acid analog, tartaric acid, and a compound assumed to be arabinose. From their case report, Shaw et al. made three assumptions: (1) The metabolites are produced by an overgrowth of a fungus or fermenting yeast such as *Candida albicans*. (2) The overgrowth of fungus or yeast in individuals with autism occurs in the gastrointestinal system rather than the urinary tract. (3) The growth interferes with normal metabolism and produces symptoms of autism. None of these hypotheses have been confirmed by independent investigators in peer-reviewed studies, and some are considered biologically implausible (Lord 2003).

Goals and Objectives

The goal of antiyeast therapy is to rid the body of yeast. William Shaw (2008) recommends probiotics, antiyeast diet, and antifungal products as antiyeast therapies.

Treatment Procedures

Shaw (2008) offers tests for yeast overgrowth through his Great Plains Laboratory and recommends probiotics, antiyeast diet, and antifungal products as antiyeast therapies. Probiotics can be found in yogurt or purchased as supplements from pharmacies or health food stores. An antiyeast diet is a low-sugar diet with the simple mantra: “If it’s sweet, don’t eat”. Nonprescription antifungal supplements include garlic, oregano, caprylic acid, MCT oil, colloidal silver (although Shaw

acknowledges that this may be dangerous), lactoferrin, and biotin. Prescription antifungal drugs that are considered safe because they are poorly absorbed from the intestines include nystatin and amphotericin B. Other prescription antifungals which Shaw does not consider to be as safe are Sporanox (itraconazole) and Lamisil (terbinafine). The use of any prescription drug should be closely supervised by a board-certified physician.

Efficacy Information

Dr. Shaw reports that combining diet and antifungals “double[s] the effectiveness of diet alone in eliminating yeast overgrowth.” However, he does not cite any evidence for a link between autism and yeast and does not report on the validity of his lab tests. Furthermore, he concedes that no “formal assessments” are available to address the effects of the diet and antifungals on the core symptoms of autism (2008). At this time, no clinical trials have been performed, and only anecdotal evidence supports the application of antiyeast diets or medications. Levy and Hyman (2008) have categorized antifungal therapy as a Grade C treatment for autism, supported only by low-quality evidence. According to a consensus statement from an expert panel of clinicians, antiyeast therapy is not recommended for patients with autism spectrum disorders at this time (Buie et al. 2010).

Outcome Measurement

Antiyeast treatment is intended to reduce autism symptoms and improve adaptive functioning. Therefore, if clinical trials of antiyeast therapy are undertaken, outcome measures should include measures of autism symptoms such as the ADOS and measures of adaptive behavior such as the Vineland. Also, because the mechanism by which the treatment is postulated to work is to reduce intestinal yeast overgrowth, well-validated measures of intestinal yeast should be included.

Qualifications of Treatment Providers

A physician should be contacted before beginning an antiyeast therapy. The use of antifungal medications should have ongoing supervision from a board-certified physician.

Anxiety

Christie Enjey Lin
Departments of Education and Psychiatry, Child and Adolescent Psychiatry, University of California, Los Angeles, CA, USA

Synonyms

[Fear](#); [Worry](#)

Definition

Anxiety is a psychological and physiological state characterized by cognitive (e.g., recurrent or obsessive thoughts), somatic (e.g., headache, dizziness, nausea), affective (e.g., dysphoria or negative mood), and behavioral (e.g., trembling, pacing, or restlessness) responses that arise as a result of a perceived threat to the individual. Evolutionarily, these responses are adaptive in allowing individuals to prepare themselves to either flee or fight when faced with a threat, increasing the likelihood of survival. Although periodic anxiety experienced at moderate levels is common to most individuals and can be adaptive, irrational or extreme anxiety over an extended length of time may be indicative of an anxiety disorder. Several studies have shown that children with a pervasive developmental disorder (PDD) exhibit rates of anxiety disorders significantly higher than typically developing children. In addition, it has been speculated that some core autism symptoms may be driven or exacerbated by anxiety and that some anxiety disorder symptoms overlap with PDD features such as perseverative thought and speech.

Definition and Historical Background

The presence of anxiety in individuals with autism has been recognized since the original description by Leo Kanner (1943), who noted that a number of children from his original sample experienced anxiety in response to particular objects and situations and also in response to sensory stimuli such as loud sounds or mechanical noises. Kanner remarked that children with autism displayed an “anxiously obsessive desire for the maintenance of sameness” (p. 245) and further speculated that

some of the core autism features might be, at least in part, driven by high levels of anxiety. Almost 50 years ago, Rutter (1970) first reported depressive symptoms in a follow-up of an adolescent with autism. Despite these early descriptions and clear indications of pervasiveness and clinical impact, anxiety and depression have become a focus of autism research only in the past 20 years.

Epidemiology

Anxiety

Anxiety has been found to be significantly more prevalent and severe in autism when compared to both the general population (Kim et al. 2000) and a range of other neurodevelopmental and neuropsychiatric disorders, including, but not limited to, Down syndrome (Evans et al. 2005), specific language impairment (Gillott et al. 2001), and Williams syndrome (Rodgers et al. 2012b; Uljarević et al. 2018). Although exact prevalence has varied widely across studies, several relatively recent large-scale studies and systematic reviews have suggested that at least 40% of children and adolescents with autism meet the criteria for clinically significant anxiety (van Steensel et al. 2011; see also White et al. 2009). Prevalence of anxiety in adulthood is less well explored; however, it is clear that it is highly prevalent with recent studies suggesting that up to 60% of adults with autism may be affected (Buck et al. 2014; Lever and Geurts 2016; Uljarević et al. 2019). Results regarding the prevalence of specific anxiety disorders have been mixed. A meta-analysis by van Steensel et al. (2011; see also van Steensel et al. 2014) has suggested specific phobias (29.7%), obsessive-compulsive disorder (OCD; 17.4%), social phobia (16.6%), generalized anxiety disorder (GAD; 15.4%), separation anxiety disorder (9.0%), and panic disorder (1.8%) as the most frequent types of anxiety observed in the autism population. When discussing the prevalence of anxiety subtypes, it is important to note that the above reviewed studies relied on DSM-IV TR anxiety categories. To the best of our knowledge, studies are yet to explore the prevalence of DSM-5 anxiety subtypes. Importantly, several

studies (Halim et al. 2018; Lau et al. 2019; Kerns and Kendal 2012; Kerns et al. 2014) have also described a range of atypical fears and worries that, while common and clinically impactful in autism, do not fit within DSM frameworks.

Depression

Similar to anxiety, reported rates of depression have been highly variable across studies. In their meta-analysis of 66 studies, Hudson et al. (2019) found that rates of depressive disorder were highest when individuals were required to report their own symptoms or when a standardized interview was used, with lifetime rates ranging from 28.5% to 48.6% and current rates from 15.3% to 25.9%. Moreover, individuals with autism were four times more likely to experience lifetime depression than typically developing individuals (e.g., 11.7% to 16.6% in the United States) (Kessler et al. 2005; Merikangas et al. 2010). However, in their meta-analysis of co-occurring mental health diagnoses in autism which included 65 studies, Lai et al. (2019) reported an overall pooled prevalence for current depressive disorders of 11%. In a third meta-analysis, Hollocks et al. (2019) reported pooled current and lifetime rates of depressive disorder of 23% and 37%, respectively, although their analysis included fewer studies overall (29 studies). Finally, it is worth noting findings from a large population-based cohort study by Rai and Heuvelman et al. (2018b), which utilized data from the Stockholm Youth Cohort. Participants included 2,927 individuals with autism without intellectual disability, 1,146 with autism and intellectual disability, and 219,769 without autism, followed up to 27 years of age. Compared to the general population, 19.8% of individuals with autism had a diagnosis of depression by 27 years compared to 6% of the general population, and those with autism who did not have an intellectual disability had a greater relative risk (RR) of a depression diagnosis than those with co-occurring intellectual disability (adjusted RR 4.28 and 1.81, respectively). Furthermore, compared to their siblings without autism, those with autism had a twofold risk of a depression diagnosis in early adulthood.

Suicidal Ideation and Behavior. The prevalence of suicide is much higher in autism than in non-autism samples (Cassidy et al. 2018b; Hedley and Uljarević 2018; Hirvikoski et al. 2016). Systematic research studies of both autism and population samples, supplemented by personal accounts from autistic individuals, show that autistic traits are associated with a significantly increased vulnerability to suicidal ideation, suicide attempts, and deaths by suicide in autism (Adams 2019; Cassidy and Rodgers 2017; Hedley and Uljarević 2018; Luterman 2019; South et al. *in press*). This vulnerability seems to result from a range of individual and environmental factors including perceived social isolation (Cassidy and Rodgers 2017; Hedley et al. 2018b; Pelton and Cassidy 2017), pressure to “camouflage” autism traits to match societal norms (Hull et al. 2017; Leedham et al. 2019; Beck et al. *in press*), and difficulty accessing health services (Camm-Crosbie et al. 2018). Proposed relationships among these variables are complex and in need of further study (Culpin et al. 2018; Gotham et al. 2018; Hedley et al. 2017b; Maddox et al. 2017).

While mental health concerns such as depression and anxiety are associated with suicide risk both generally and in autism (Cassidy et al. 2014; Hedley et al. 2018b), links between mental health concerns, non-suicidal self-injury, and suicidal thoughts and behaviors in autism are not straightforward (Hannon and Taylor 2013; Hedley and Uljarević 2018; Maddox et al. 2017; Richa et al. 2014; Segers and Rawana 2014). One emerging factor that requires further study is that rates of suicide are more uniform between males and females in autism (Hirvikoski et al. 2016; Kirby et al. 2019), in contrast to non-autism populations where men die by suicide more frequently than women. Suggested reasons for more equal gender balance might include factors such as later identification and diagnosis in women and social and emotional differences. For example, increased social motivation and awareness in women with autism may exacerbate feelings of isolation (Ratto et al. 2018; White et al. 2017). Higher rates of camouflaging in women with autism may contribute critical vulnerability (Beck et al. *in press*; Cassidy et al. 2018b; Ratto et al. 2018; White et al. 2017).

Natural History and Outcomes

Anxiety and depression follow distinct and well-established developmental trajectories in the general population. While depression rates show an increase from young to middle adulthood followed by a protracted decline towards older adulthood (Kessler et al. 2005; Suttin et al. 2013), anxiety shows an earlier onset and steeper increase with higher rates observed in young and middle adulthood and moderate decline thereafter (Lee et al. 2016). Sex differences in rates of anxiety and depression are well established such that males experience lower levels of both disorders (Kessler et al. 2005). Of note, sex differences become more pronounced with increasing age (Kessler et al. 2005).

Only four studies to date have explored the course of anxiety and depression across the lifespan in autism. Davis et al. (2011) found that anxiety levels were higher in a group of children with autism aged 3–16 years ($n = 34$) when compared to a group of toddlers ($n = 40$), but lower than in a group of 30 individuals aged 20–48 years, which in turn showed lower anxiety levels than a smaller group ($n = 27$) of individuals aged between 49 and 65 years. Roy et al. (2015) reported lower frequency of anxiety and depression in 26 younger adults (age range: 20–40 years) when compared to 24 older adults (age range: 40–62 years) with autism. A study by Lever and Geurts (2016) explored the pattern of co-occurring psychiatric disorders, including anxiety and depression, in 52 younger (19–38 years), 72 middle-aged (39–54 years), and 48 older (55–79 years) adults with autism and reported that although the severity of both anxiety and depressive symptomatology was high across all age groups, the older group had significantly lower scores compared to the two younger adult groups. Finally, a recent study by Uljarević et al. (2019) examined age trends in anxious and depressive symptoms in a large, cross-sectional sample of 255 adolescents and adults with autism and found that at any life stage, more than one-third of participants reported clinically significant anxiety and depression. Uljarević and colleagues noted a slight increase in the severity of both

anxiety and depression from adolescence to middle adulthood and then a slight decrease in older adulthood; however, these changes were not statistically significant. Although longitudinal studies are missing, it is clear that both anxiety and depression remain prevalent problems across the lifespan of autism.

Anxiety and depression negatively impact concurrent and long-term outcomes. More specifically, elevated levels of anxiety and depression are associated with increased severity of restricted and repetitive behaviors (Uljarević et al. 2017a), a range of externalizing problems (Mattila et al. 2010), loneliness (White and Roberson-Nay 2009), suicidality (Hedley and Uljarević 2018), higher support needs and poorer employment outcomes (Hedley et al. 2017b), and increased parental levels of affective symptoms (Kerns et al. 2015).

Pathophysiology

Research to date has mainly focused on the role of (i) demographic factors, (ii) chronological and developmental age/cognitive functioning, and (iii) autism-specific traits and symptoms, as potential risk factors underlying the high rates of anxiety and depression in autism. More recently, studies have started to explore the role of transdiagnostic risk factors, most notably emotion regulation and intolerance of uncertainty, that have been found to be associated with a range of mental health outcomes across normative and atypical development.

Demographic Factors

A familial history and female sex/gender have been associated with higher prevalence and severity of anxiety and depression (Hedley et al. 2018b; Lai et al. 2019; Rai et al. 2018b; Uljarević et al. 2019). Of note, while adult samples show higher rates of depression in females than males (Hedley et al. 2018a; Lai et al. 2019), rates appear to be more similar for males and females during the school years (Greenlee et al. 2016). A recent meta-analysis by Hudson et al. (2019) reported that being White was associated with higher

lifetime prevalence rates of depression; however, this may also reflect underreporting or underdiagnosis in other races. Effects of race and ethnicity on the rates of anxiety have not been explored in detail.

Cognitive Functioning

Higher cognitive functioning has been associated with higher prevalence and severity of both anxiety (Hallett et al. 2013; Mayes et al. 2011; but see Duvekot et al. 2017 and Eussen et al. 2013 for nonsignificant findings) and depression (Hudson et al. 2019). However, a positive relationship between cognitive functioning and anxiety and depression may reflect expressed rather than experienced symptom levels (Strang et al. 2012). This assertion is supported by the fact that verbal intelligence quotient (IQ), as compared to non-verbal IQ, is more strongly associated with greater levels of anxiety (Gotham et al. 2013; Mayes et al. 2011).

Core Autism Symptoms

It has been hypothesized that core autism symptoms may increase the frequency and severity of everyday stressors, both directly and indirectly (Wood & Wood and Gadow 2010). Studies exploring the relationship between overall autism severity and anxiety have produced inconsistent result – positive (Wigham et al. 2015), negative (Eussen et al. 2013), and lack of significant relationships (Hollocks et al. 2016) have all been reported. However, given the multidimensional and multifactorial nature of autism, studies focusing on the relationship between anxiety and more fine-grained aspect of autism phenotype have produced more consistent results. For instance, preserved social motivation in combination with impaired social and communication skills may lead to repeated social failures, increased emotional pain, and isolation, which, in turn, contributes to the emergence of anxiety (Bellini 2004; Pickard et al. 2017; Phillips et al. 2019; Uljarević et al. 2020). Repetitive behaviors, in particular, insistence on sameness, have been suggested to have an important and somewhat circular role in the development and maintenance of anxiety. More specifically, drawing on the findings from

the normative literature, Uljarević, Richdale, McConachie, and colleagues (2017b; see also Leekam et al. 2011) hypothesized that although during early development insistence on sameness serves to constrain the unpredictability of the environment thus warding off fears and anxieties, over time, due to their inflexible and restrictive nature, these behaviors preclude development of more adaptive forms of self-regulation and thus lead to maintenance of anxiety. Indeed, insistence on sameness has been consistently associated with anxiety across a number of studies (see Leekam et al. 2011; Rodgers et al. 2012a; Gotham et al. 2013; for an overview). Finally, atypical sensory features, in particular sensory hypersensitivity, have been consistently implicated as risk factors for both overall anxiety (Kerns et al. 2014; Lidstone et al. 2014; Uljarević et al. 2016) and anxiety subtypes including specific phobias, GAD, and social phobia (Bitsika et al. 2016, 2019).

Severity of autistic traits has been found to predict depressive symptoms in autism (Hedley et al. 2018a; Rai et al. 2018a), the general population, and individuals experiencing first-episode psychosis (Uptegrove et al. 2018). Rai et al. (2018a) found that 10-year-old children with autism or high levels of autistic traits, particularly social communication impairments, reported higher depressive scores than the general population. The depressive levels remained elevated and on an upward trajectory until 18 years. Bullying accounted for a large portion of risk, and there may well be an interaction between autistic traits, social communication difficulties, and depression (Rai et al. 2018a). Similarly, psychosocial risk factors that may be exasperated by autism, such as loneliness and lack of friendships and social support, have also been shown to predict depressive scores (Hedley et al. 2018b; Mazurek 2014).

Transdiagnostic Factors

Emotion regulation is a complex process that is goal-directed and aims to modify the intensity, duration, and types of emotions experienced (Eisenberg and Spinrad 2004). Research findings in non-autistic populations indicate that the habitual use of certain strategies to regulate negative

emotions (e.g., expressive suppression, avoidance, denial, negative rumination) is related to an increase in internalizing symptoms including anxiety and depression (Aldao et al. 2010; Gross and John 2003). As a result, these strategies are viewed as maladaptive. The habitual use of other strategies to regulate positive emotions (e.g., savoring) and negative emotions (e.g., emotional acceptance) is related to reduced negative emotions, increased positive emotions, and better mental health (Aldao et al. 2010; Campbell-Sills et al. 2006; Troy et al. 2013). Hence, these strategies are typically categorized as adaptive.

Overall, research studies have found that individuals with autism use less adaptive emotion regulation strategies than individuals without autism (e.g., Bruggink et al. 2016; Rieffe et al. 2014; Samson et al. 2015). Findings around maladaptive strategy use are less consistent with studies showing more (e.g., Jahromi et al. 2012; Mazefsky et al. 2014), similar (Rieffe et al. 2014), and less frequent use of maladaptive strategies in autism (Samson et al. 2015). The majority of studies reporting higher internalizing and externalizing symptoms in those with autism relative to controls found individuals with autism used more maladaptive strategies and/or less adaptive ones (Cai et al. 2018c). Recent research examining interactions between adaptive and maladaptive emotion regulation strategy use in autism suggest that the higher use of an adaptive strategy might be a protective factor for psychological well-being in individuals who also show high use of maladaptive strategies (Cai et al. 2019, 2018b).

Intolerance of uncertainty is defined as the “dispositional incapacity to endure the aversive response triggered by the perceived absence of salient, key, or sufficient information, and sustained by the associated perception of uncertainty” (Carleton 2016, p. 31). Individuals who are high in intolerance of uncertainty tend to believe uncertainty is negative and threatening, find ambiguous situations stressful and avoid them, and have problems functioning in uncertain situations (Ladouceur et al. 2000). A meta-analysis by Gentes and Ruscio (2011) has provided robust evidence for the relationship between intolerance of uncertainty, anxiety, and

major depressive disorders. Although the role of intolerance of uncertainty in autism has started to be explored only relatively recently, emerging findings mirror results from the general population. More specifically, it has been consistently reported that children and adults with autism experience higher levels of intolerance of uncertainty when compared to non-autistic controls and that intolerance of uncertainty is associated with anxiety and depression in autism (Boulter et al. 2014; Cai et al. 2018a; Maisel et al. 2016).

Given that individuals with autism present with a maladaptive patterns of emotion regulation strategy use (Cai et al. 2018c) and higher levels of intolerance of uncertainty (Maisel et al. 2016), and both emotion regulation and intolerance of uncertainty strategy use are independently associated with affective symptoms in autism (Samson et al. 2015; Wigham et al. 2015), it is important to clarify the nature of the inter-relationship of intolerance of uncertainty and emotion regulation strategy use in predicting symptoms of anxiety and depression. Indeed, a recent study found that intolerance of uncertainty mediated the relationships between emotion regulation strategy use and symptoms of anxiety and depression (Cai et al. 2018a).

Evaluation and Differential Diagnosis

Depression and anxiety in autism might present differently compared to expression in non-autism clinical groups or might be less apparent. These differences can be attributed to several factors. Firstly, there is considerable overlap between the core autism symptoms and those attributed to anxiety and depression. For instance, while the lack of social approach and engagement can be considered as a symptom of social phobia, it can also be a manifestation of the social communication impairment that characterizes autism. Thus, while it is easy to identify anxiety disorder that manifests with social avoidance in individuals without autism, in the autism population, this symptom might be interpreted as a part of the core autism symptomatology. Consequently, co-occurring mental health disorders can remain undiagnosed and untreated (Uljarević

et al. 2016b). Further, individuals with autism might present with idiosyncratic symptoms including unusual specific phobias (e.g., vacuum cleaners, toilets), fears of change, or novelty; or depression might be expressed through reduction in circumscribed interests (Kerns and Kendal 2012; Uljarević et al. 2016a).

To address these issues, an increasing number of studies have focused on exploring the relevance of existing anxiety and depression measures in autism. For instance, a systematic review by Wigham and McConachie (2014) identified the Spence Children's Anxiety Scale (Spence 1998), the Revised Children's Anxiety and Depression Scale (Chorpita et al. 2000), and the Screen for Child Anxiety-Related Emotional Disorder (Birmaher et al. 1997) as robust outcome measures for Cognitive Behavior Treatment Trials. However, several studies failed to provide the support for the original factor structure of the Spence Children's Anxiety Scale in autism samples (Glod et al. 2017; Jitlina et al. 2017; Magiati et al. 2017). Cassidy et al. (2018a) conducted a systematic review and evaluated instruments that had been used to assess depression in adults with and without autism and without co-occurring intellectual disability. Only one study provided sufficient data to examine psychometric properties in people with autism, leading the authors to conclude that there was only weak support for the use of the Beck Depression Inventory (BDI-II) (Beck et al. 1996) in this population. With regard to other instruments, Uljarević, Richdale, McConachie, and colleagues (2017b) examined the factor structure and psychometric properties of the Hospital Anxiety and Depression Scale (HADS) (Zigmond and Snaith 1983) in representative sample of older adolescents and young adults with autism from the United Kingdom (UK) and Australia. Factor structure was similar to that found in the general population, internal consistency was acceptable, convergent validity was excellent, and divergent validity was found to be acceptable, thus providing support for the HADS in this population.

Given the variable performance of anxiety and depression measures originally designed for the general population when used in autism, and the noted specificity of symptom expression in

this population, several attempts have been made to modify existing instruments. For example, Rodgers et al. (2016) created the Anxiety Scale for Children – autism spectrum disorder (ASC-ASD) by modifying the Revised Children's Anxiety and Depression Scale (RCADS; Chorpita et al. 2000) to incorporate items related to intolerance of uncertainty, sensory oversensitivity, and phobias. The newly developed scale had good internal consistency, validity, and 1-month test-retest reliability. Kerns et al. (2014, 2015, 2016) have also shown that the Autism Spectrum Addendum (ASA) to the Anxiety Disorders Interview Schedule (ADIS; Silverman and Albano 1996) had satisfactory psychometric properties and convergent and discriminant validity in both low anxiety (Kerns et al. 2014) and non-treatment seeking (Kerns et al. 2015) samples of children with autism.

In summary, given that on the one hand, autism-related behaviors can be mistakenly interpreted as signs of a co-occurring anxiety and depression, and on the other hand, anxiety and depression symptoms can be expressed in atypical ways in individuals with autism, and either missed or ascribed to the underlying autism, careful consideration about how best to consider and capture the differential diagnoses of anxiety and depression in individuals with autism is needed. Design of new measures and improvements in the performance of existing measures are currently a priority in the field.

Treatment

Both psychopharmacological and psychosocial intervention approaches have been used to treat anxiety and depression in autism (White et al. 2009; Selles and Storch 2013; Vasa et al. 2014).

Pharmacological Treatments

Pharmacological treatments remain the primary method for treating mental health problems in individuals with autism (Kerns et al. 2016). Pharmacological treatments that have been studied include antidepressants and anxiolytics, but findings regarding treatment effects have been mixed and there is a lack of well-controlled studies looking at anxiety- and depression-

specific treatment effects (Selles and Storch 2013). It is important to highlight the fact that despite somewhat limited evidence concerning the efficacy of pharmacological treatments for anxiety and depression in autism, a review of medical and pharmacy claims data found that 64% of 33,565 children with autism were taking at least 1 psychotropic medication and 35% had evidence of polypharmacy with a median use length of 346 days (Spencer et al. 2013).

Psychosocial Treatments

Cognitive behavioral therapy (CBT), administered individually or in a group format, and mindfulness therapy, may be useful in treating anxiety and depression in individuals with autism (Kerns et al. 2016). One meta-analysis which examined the efficacy of CBT to treat affective disorders in children, adolescents, and adults with autism found CBT was superior to control conditions, returning medium effect sizes ($g = 0.45\text{--}0.59$) (Weston et al. 2016). Building on this evidence as well as robust findings from non-autistic populations that show emotion regulation is malleable to treatment (e.g., Blackledge and Hayes 2011), it has been proposed that targeting emotion regulation impairments may be an effective approach in treating anxiety and depression in the autism population (Weiss et al. 2014). Indeed, researchers have started designing intervention programs to improve emotion regulation in autism (Thomson et al. 2015). Programs aimed at reducing intolerance of uncertainty have also been developed (Rodgers et al. 2016, 2018). Given the inter-relationships between emotion regulation, intolerance of uncertainty, and psychopathology, we suggest that developing interventions aimed at improving the former two constructs may be more effective for improving affective symptoms in individuals with autism than just targeting one construct at a time.

Conclusion

Although the prevalence rates of anxiety and depression in autism have varied significantly across studies, based on the most up-to-date reviews and large-scale studies, it is clear that

both disorders are highly prevalent. The rate of current depressive disorder in autism is likely to range from 11% to 26%, and lifetime rates from 28% to 48%. The rate of anxiety disorders is likely to be around 40% in children and adolescents and up to 60% in adults. It is somewhat difficult to draw firm conclusions about the exact age-related trends of anxiety and depression in autism due to the fact that above reviewed studies were all cross-sectional rather than longitudinal and utilized different measurement instruments. However, it is clear that both anxiety and depression remain prevalent across the lifespan. Given that anxiety and depression have a significant negative impact on the functioning of individuals with autism and their families, often over and above the contribution of core-autism traits and developmental level, clarifying the link of autism with anxiety and depression is currently considered to be a priority in the field.

Anxiety Disorders

César Soutullo

Child and Adolescent Psychiatry Unit,
Department of Psychiatry and Medical
Psychology, University of Navarra Clinic,
Pamplona, Spain

Synonyms

Affective disorders (includes mood and anxiety disorders); Neurotic disorders (DSM-II terminology)

Short Description or Definition

Fear is a normal brain state, a physiologic response in response to a threat, or a dangerous or unexpected stimuli that serves as a warning system to maintain the individual and/or group safety. It is mediated by the activation of orbitofrontal cortex,

anterior cingulate gyrus, hippocampus and amygdala limbic circuits. When the fear occurs in the absence of a threat is called anxiety. Both fear and anxiety are normal reactions to danger. The physiologic normal response of fear and anxiety triggers a “fight, freeze, or flight response” that has been preserved throughout evolution. If anxiety is triggered by a non-dangerous stimuli, or it is too intense or persistent, or it creates impairment, it can be considered as an anxiety disorder. Symptoms are of a cognitive (e.g., worry thoughts), physiological (e.g., tachycardia), or behavioral (e.g., avoidance) nature. Anxiety disorders and mood disorder form the category of affective disorders (Revised in Soutullo and Figueroa 2010).

Categorization

There are several types of anxiety disorders, depending on the stimuli that trigger the anxiety:

- Separation anxiety disorder (SAD)
- Panic disorder
- Agoraphobia
- Generalized anxiety disorder (GAD)
- Simple Phobia that has five subtypes:
 - Animal
 - Environmental (heights, storms, etc.)
 - Pain (injections, blood, injuries, surgeries)
 - Situational (flights, elevators, closed environments, tunnels)
 - “Other types” (choking, vomiting, having an illness)
- Social phobia
- Obsessive-compulsive disorder (OCD)
- Posttraumatic stress disorder (PTSD)

Epidemiology

Anxiety disorders as a group are the most frequent psychiatric disorders in children and adolescents. The epidemiology varies across development. Usually simple phobias and separation anxiety appear first, and then social phobia, GAD, and panic disorder. Some authors suggest that the different anxiety disorders across childhood and

adolescence represent only a developmental variation of the disorder. Available data suggests that 2.8–27% of children and adolescents may have some form of anxiety disorder (Krain et al. 2007). Anxiety disorders are usually more frequent in females, and interestingly, female preponderance emerges before puberty, except in GAD, that only becomes more frequent in females after adolescence (Krain et al. 2007).

Prevalence of GAD is 6.5% in preschoolers, 3.8% in children, and 6.6% in adolescents; of social phobia 3.4% in preschoolers, 1.3% in children, and 1.1% in adolescents; of separation anxiety disorder is 2.4% in preschoolers, 4.1% in children, and 1.4% in adolescents; of simple phobia 1.9% in preschoolers, 5.8% in children, and 4.1% in adolescents; and of panic disorder 0.8% in children, and 2.7% in adolescents. The lifetime prevalence rate of OCD is between 1% and 4% (Keeley and Storch 2009). The mean age of onset is 4.1 years for simple phobia, 4.3 for separation anxiety, 5.3 for agoraphobia, 6 for social phobia, 6.3 for GAD, 6.5 for PTSD, and 8.5 for panic disorder.

Natural History, Prognostic Factors, Outcomes

There is a statistically robust, but modest in effect size (Odds Ratio: 2.0:4.0), association between pediatric anxiety disorders and a range of adult psychiatric disorders, such as mood and anxiety disorders. The most robust association appears to be between GAD and major depression, and anxiety disorder, especially panic disorder (Krain et al. 2007).

Clinical Expression and Pathophysiology

The key characteristics of the different anxiety disorders are (Tables 1 and 2):

- 1. Separation anxiety disorder: Excessive worries concerning separation from loved one, frequently associated with physical symptoms, school avoidance and worries about the loved ones, or about getting lost.

- 2. Social phobia: Fear on social situations that are avoided or endured.
- 3. GAD: Excessive uncontrollable worries about multiple issues during most of the time.
- 4. Specific phobia: Extreme fear and avoidance of specific situations or objects.
- 5. Panic disorder: Unexpected panic attacks, brief in time, with associated physical and psychological symptoms, and fear of having another attack in the future.
- 6. PTSD: Anxiety symptoms after a traumatic event, with associated autonomic hyperarousal, avoidance of the situation, and intrusive memories.
- 7. OCD: Obsessions (intrusive ego-dystonic thoughts) and associated compulsions (behaviors) aimed to reduce anxiety.

Anxiety-related disorders are among the most frequent presenting problems in the clinical setting in children with ASD (Tables 1 and 2).

The etiology and pathophysiology of anxiety is still under study, but we know that there are four factors involved in the development of an anxiety disorder: (1) genetic and environmental influences, (2) the neural circuits underlying emotion process, (3) core psychological processes, and (4) broad behavioral tendencies, including temperament. There are important genetic components in various forms of anxiety. Genetic and environmental influences are likely to shape more basic psychological processes which in

Anxiety Disorders, Table 1 Content of anxious thoughts for specific anxiety disorders

Anxiety disorder: worries, anticipated harm
SAD: Being separated from caretaker, harm to self or caretaker
PD: Being unable to escape the current situation, dying, losing control, going crazy
Social phobia: Negative social judgment embarrassment, negative evaluation, or rejection
PTSD: Posttraumatic event, reexperiencing traumatic event
OCD: Contamination, contracting a disease, doubt, catastrophic outcome
GAD: Routine life issues such as academic performance or social interactions, wide range of possible negative outcomes (e.g., failure, rejection)

Anxiety Disorders, Table 2 Somatic symptoms of anxiety included in the DSM-IV-TR (Keeley and Storch 2009)

System and symptoms
Cardiac
Tachycardia
Palpitations/Heart pounding
Chest pain
Shortness of breath
Gastrointestinal (GI)
Dry mouth
Difficulty swallowing
Nausea/vomiting, diarrhea
GI discomfort
Urogenital
Frequent urination, tenesmus
Respiratory
Shortness of breath
Smothering sensation
Choking sensation
Neurologica
Numbness/tingling
Tremor/shaking
Syncopal episodes/fainting
Sleep
Insomnia
Reluctance/refusal to sleep alone
Nightmares
Sleeptalking/sleepwalking
Excessive tiredness
Dermatological/temperature regulation
Sweating
Hot flashes
Chills
Cold, clammy hands
ENT
Dizziness
Lightheadedness
Feeling unsteady
Others
Increased startle response
Muscle tension

turn influence risk for anxiety. Despite the evidence for genetic contribution, anxiety disorders involve a large environmental component. Parents with anxiety may have distinctive child rearing or parenting practices, and may encourage or train their children to maladaptive patterns of responding to ambiguous situations (Keeley and Storch 2009).

Fear is regulated by connections between pre-frontal cortex (PFC) and the amygdala. When these circuits are altered (by a genetic or by an environmental overactivation), the child perceives a neutral stimuli as dangerous. In PFC the two areas involved in anxiety and fear are the orbitofrontal cortex (OFC) that makes a representation of both negative and positive reinforcers, and the anterior cingulate cortex (ACC), that regulates the emotional response. In addition to these responses, an activation of the amygdala activates:

- The HPA axis, and the hypothalamus secretes CRF (corticotrophin releasing factor), induces the secretion of ACTH, that will induce the secretion of cortisol and adrenaline in the adrenal gland, and causes hyperglycemia and tachycardia, needed for the brain and muscles to respond to danger.
- The parabrachial nuclei that increases respiratory frequency and may cause a sensation of shortness of breath similar to an asthma attack.
- The locus coeruleus, that also releases adrenaline, that raises blood pressure, pulse, activates sweating, and induces tremor (Revised in Soutullo and Figueroa 2010).

Evaluation and Differential Diagnosis

Evidence-based methods of evaluation include diagnostic interview schedules, rating scales, observations, and self-monitoring forms.

Diagnostic Interviews

Diagnostic interviews are reliable and valid instruments to facilitate diagnostic decisions consistent with DSM-IV-TR criteria. These clinician-administered structured diagnostic interviews assess for anxiety disorders and for the presence of other psychiatric disorders. However, these interviews require trained clinicians, and can be time-consuming and expensive (lasting 60–120 min). The most common diagnostic

interviews used in the diagnosis of anxiety disorders include:

1. The *Anxiety Disorders Interview Schedule for DSM-IV: Child and Parent Versions*
2. *K-SADS-PL: Kiddie Schedule for Affective Disorders and Schizophrenia-Present and Lifetime Version*
3. *SCID: Structured Clinical Interview for DSM-IV*

Rating scales: Self-report or parent-report rating scales require minimal training, are easy to administer, can be completed and scored quickly, are useful screening devices, and are easily readministered to capture clinical change over time.

General Anxiety Rating Scales

1. The *SCARED* (Screen for Child Anxiety Related Emotional Disorders-Revised) has five subscales (Panic/Somatic, Separation Anxiety, Social Phobia, General Anxiety, and School Phobia) that help to identify specific anxiety symptoms.
2. The *MASC* (Multidimensional Anxiety Scale for Children) is another commonly used rating scale of general anxiety symptoms with four subscales (Physical Symptoms, Harm Avoidance, Social Anxiety, and Separation/Panic) and an Anxiety Disorders Index, which includes items found to differentiate children with and without an anxiety disorder.
3. The *Fear Survey Schedule for Children-Revised* is a commonly used measure to assess childhood fears, with five subscales: Fear of Failure/Criticism, of the Unknown, of Injury and Small Animals, of Danger/Death, and Fear of Medical Situations.

Syndrome-Specific Anxiety Measures

1. The Social Anxiety Scale for Children-Revised
2. The Children's Yale-Brown Obsessive-Compulsive Scale-Child Report and Parent Report
3. Trauma Symptom Checklist for Children to assess PTSD Symptoms

Observational and Self-monitoring Methods

Direct Observation

1. Social evaluative tasks: In which a child is observed performing in a social situation (e.g., public speaking)
2. Behavioral avoidance tasks: In which a child's response to being exposed to a fear or anxiety-provoking stimuli is observed
3. Parent-child interaction tasks: In which parent and child are observed in a problem-solving task

Self-monitoring Procedures

This is a method to identify and quantify symptoms and behaviors using self-rated via diary-like entries.

Treatment

Practice parameters for the treatment of children with anxiety disorders recommend a multimodal approach to treatment, and comprehensive care should include consideration of:

- Psychoeducation
- Cognitive-behavioral psychotherapy (CBT)
- School consultation
- Family therapy
- Psychodynamic psychotherapy
- Pharmacotherapy (AACAP 2007)

The psychological interventions that have the most empirical support for childhood anxiety to date are *behavioral* and *cognitive-behavioral* interventions and *pharmacotherapy* with selective serotonin reuptake inhibitors (SSRIs) in the short-term treatment of childhood anxiety (AACAP 2007).

Behavioral and Cognitive-Behavioral Psychotherapy (CBT)

Cognitive-behavioral therapy (CBT) has proven to be effective in treating children and adolescents with anxiety disorders. CBT includes:

1. A cognitive-restructuring component
2. Modeling

3. Relaxation skills training
4. Homework
5. Contingency management
6. Most importantly, exposure to feared situations

The exposure (imagined, virtual, or real) is an opportunity for the patient to practice newly learned coping skills in a safe and controlled environment. The cognitive part helps children to change the thinking patterns that support their fears, and the behavioral part helps them to change the way they react to anxiety-provoking situations.

Despite some methodological limitations, mainly the use of a waiting list as a control group, CBT has demonstrated efficacy in the treatment of children with social phobia, GAD, and SAD, in two 16-week randomized controlled trials (Kendall et al. 1997). CBT with a family-based component was also effective, and had added benefits, particularly for younger female children, and treatment gains were maintained at 6-year follow-up (Barrett et al. 2001).

Exposure-based behavioral therapy has been used to treat specific phobias and OCD exposing the child gradually to the object or situation that is feared, perhaps at first only through pictures or tapes, then later face-to-face. Often the therapist will accompany the person to a feared situation to provide support and guidance. CBT is undertaken when the child decides he is ready for it and with his permission and cooperation. To be effective, the therapy must be directed at the person's specific anxieties and must be tailored to his or her needs. There are no side effects other than the discomfort of temporarily increased anxiety. CBT or behavioral therapy often lasts about 12 weeks. It may be conducted individually or with a group of people who have similar problems. Group therapy is particularly effective for social phobia. Often "homework" is assigned for participants to complete between sessions. There is some evidence that the benefits of CBT last longer than those of medication for people with panic disorder, and the same may be true for OCD, PTSD, and social phobia. If a disorder recurs at a

later date, the same therapy can be used to treat it successfully a second time.

Pharmacotherapy with SSRIs

Several recent randomized, placebo-controlled trials of SSRIs have shown evidence for the short-term efficacy of these medications in the treatment of children with anxiety disorders, including:

- GAD (Birmaher et al. 2003; RUPP 2001; Rynn et al. 2001).
- Social phobia (Birmaher et al. 2003; RUPP 2001; Wagner et al. 2004).
- SAD (Birmaher et al. 2003; RUPP 2001)
- OCD (POTS 2004)

No randomized, placebo-controlled trials of SSRIs exist for pediatric Panic Disorder (PD) or PTSD. Uncontrolled trials of SSRIs for pediatric PD suggest that SSRI treatment results in clinically significant reductions in symptoms (Keeley and Storch 2009).

Pharmacotherapy of Anxiety in Children with Autistic Spectrum Disorders (ASD)

There is some very preliminary evidence for the efficacy of sertraline, fluvoxamine, fluoxetine, buspirone, and dextromethorphan. None of these reports included a control group or placebo arm, and the largest sample size was 22 (White et al. 2009).

SSRIs

Two children ages 6 and 13 with DSM-IV ASD and co-occurring anxiety symptoms, treated with sertraline (25–50 mg/day) improved in symptoms of anxiety (Ozbayrak 1997).

An 11-year-old girl with ASD and separation anxiety disorder improved after 8-week treatment with sertraline (150 mg/day) (Bhardwaj et al. 2005).

A 7-year-old girl with PDD-NOS and intellectual disability treated with fluvoxamine had a 15.5 point decrease in the parent-reported CARS (Childhood Autism Rating Scale), and also fewer aggressive behaviors, less nervousness, but no reduction of repetitive behaviors or anxiety.

The child's parents and teachers received concurrent training and behavior interventions, which may have contributed to behavior changes (Kauffmann et al. 2001).

A retrospective chart review of 15 outpatients with ASD treated with citalopram (5–40 mg/day for 14–621 days), found improvements in symptoms of anxiety in 10 of the 15 youth (Namerow et al. 2003).

Silveira et al. (2004) treated with fluoxetine (20 mg daily) a 6-year-old girl with ASD who was also diagnosed with selective mutism and social anxiety. After 8 weeks, her parents reported improvements in symptoms of anxiety and selective mutism.

A retrospective chart review of the effectiveness of citalopram reported that 10 of 17 children with ASD who were treated with the SSRI (5–40 mg/day) showed improvement in target symptoms (Couturier and Nicolson 2002).

Buspirone

Buitelaar et al. (1998) conducted an open trial of buspirone to treat anxiety and irritability in children with ASD. All 22 youth exhibited chronic problems with anxiety, irritability, and/or affective dysregulation. After 6–8 weeks of buspirone treatment (15–45 mg/day), 16 of the 21 patients who completed the trial showed a positive response: nine had marked improvement and seven had moderate improvement on the Clinical Global Impressions-Improvement scale (CGI-I).

Dextromethorphan

Another case study of a 10-year-old boy diagnosed with autistic disorder and GAD reported improvements in target behaviors, leaving the classroom and aggressive tantrums, following treatment with dextromethorphan 30 mg/day (Woodard et al. 2005). Dextromethorphan may have relieved discomfort associated with other illnesses, may have had secondary sedative effects, or may have helped via its glutamate receptor antagonism.

Definition

Anxiolytic medications are used to treat anxiety symptoms. The most common categories involve SSRIs, serotonin agonists, and benzodiazepines. Other medications of interest but with minimal preliminary data include anticonvulsants, glutamate antagonists, and alpha-2 adrenergic antagonists.

Historical Background

There is accumulating evidence to suggest that children and adolescents with ASD have increased comorbidity with anxiety disorders, although there exists controversy on how the diagnosis of anxiety is made in ASD and what specific anxiety disorders are prevalent in this population. In fact, there has been some discussion that certain types of anxiety symptoms may be on a continuum or difficult to differentiate from core symptom domains (e.g., social anxiety and social deficits associated with ASD).

Current Knowledge

There are limited randomized, placebo-controlled trials of anxiolytic drugs for the purposes of reducing anxiety in ASD. Preliminary efficacy for SSRIs/SNRIs, buspirone, dextromethorphan, risperidone, and alpha-adrenergic antagonists exists in this area. Only two of these studies included a control group, and the largest sample size was 31.

SSRIs: There are three children with ASD and comorbid anxiety that have responded to sertraline based on clinician ratings on case reports (Bhardwaj et al. 2005; Ozbayrak 1997). Improvements in “nervousness” with fluvoxamine were reported in a single case by Kauffmann et al. 2001. Silveira et al. (2004) reported on a single case of a 6-year-old girl with ASD, selective mutism, and social anxiety who responded to fluoxetine. Two retrospective case series of citalopram in children with ASD and anxiety symptoms reported improvements in anxiety in response to citalopram (Couturier and Nicolson 2002; Namerow et al. 2003). Of note, there is a debate in the literature about whether repetitive behaviors seen in autism are related to anxiety disorders. Two large, randomized trial studies to date have shown that SSRIs (citalopram and fluoxetine) are not effective in reducing repetitive behavior in youth with ASD.

Bupirone: There is an open-label trial of bupirone, a serotonin agonist, in 22 children with ASD with comorbid anxiety, irritability, and affective dysregulation (Buitelaar et al. 1998). Sixteen of the 22 children were rated as responders at the end of the 8-week study.

Alpha-adrenergic agonists: A small double-blind, placebo-controlled, crossover study of transdermal clonidine in seven children and two adults with ASD and “hyperarousal” reported improvements on the CGI scale (Fankhauser et al. 1992). An open-label study (Ming et al. 2008) also showed improvements in sleep latency and night awakenings.

Glutamatergic agents: A case report suggested improvements in anxiety with dextromethorphan, a weak NMDA inhibitor (Woodard et al. 2005).

SNRIs: An open-label study of mirtazapine in 26 children and young adults with ASD suggested clinically meaningful improvements in 9/26 participants based on improvements in a variety of symptoms including anxiety.

Atypical antipsychotics: In a double-blind, placebo-controlled trial of risperidone in adults with ASD, significant improvements were noted in anxiety in the risperidone group over a 12-week period versus the placebo group (McDougle et al. 1998).

There has been almost no data that examines the role of *benzodiazepines in ASD*. Oswald and Sonenklar (2007) reported that in 2002, less than 5% of ASD patients were prescribed a benzodiazepine, suggesting that this class of medications is not widely used in ASD, despite their known effectiveness for anxiety disorders. Other than being habit forming, there are also reports of paradoxical reactions with the use of benzodiazepines in this population. For example, Marrosu et al. (1987) published a case series of anxiogenic and aggressive responses to diazepam in seven children with ASD. Overall, this class of medication is less attractive for use in pediatrics and especially in children with ASD.

Future Directions

There is also a clear lack of randomized, controlled trials of anxiolytic medications for the treatment of anxiety in ASD. In addition, there is accumulating data to support the use of CBT-based programs for anxiety in this population. There seems an urgent need to identify effective medications, and even more importantly, there is need to examine how medication may facilitate the ability psychoeducational programs to teach new skills and ultimately change the trajectory of anxiety symptoms in this population.

Definition

Anxiolytic is a broad term meant to describe medications that are used to reduce anxiety. Most commonly, these include benzodiazepines and SSRIs.

Benzodiazepines are a class of medications containing several drugs used in the treatment

of insomnia, anxiety, and seizures. The benzodiazepines represent a major advance in psychopharmacology with their introduction in the 1950s. These medications have been commonly used, but are habit-forming. The benzodiazepines have not been well studied in children or adults with autism. The short-acting benzodiazepines (lorazepam and alprazolam) are sometimes used to decrease anxiety prior to medical or dental procedures in children with ASDs. The right dose given at the right time prior to the procedure can be helpful. However, adverse effects of the benzodiazepines may include disinhibition (increased impulsiveness) and poor coordination. The disinhibition can be extreme. Rather than exerting a calming effect, some children have paradoxical activation. It is usually advisable to try a test dose before the actual day of the procedure to estimate the dose and the child's response (Scahill et al. 2010). These adverse effects in the short run and the possibility of habit formation suggest that this class of medications does not have an important role to play in the treatment of adults or children with autism.

SSRIs are approved for the treatment of adults with generalized anxiety disorder, social anxiety disorder, and obsessive-compulsive disorder. But few trials with any medications focused on anxiety symptoms have been conducted in subjects with autism spectrum disorders. More recently, other medications have been added to a list of anxiolytics such as buspirone and mirtazapine, SSRIs, and specific anticonvulsants (e.g., gabapentin and pregabalin). Currently, the SSRIs are likely the most commonly used medications for the treatment of anxiety. Indeed, several of the SSRIs are approved for the treatment of adults with generalized anxiety disorder, social anxiety disorder, and obsessive-compulsive disorder. But few trials with any medications focused on anxiety symptoms have been conducted in subjects with autism spectrum disorders.

In the treatment of anxiety disorders, effective treatment usually combines cognitive behavior therapy with medication. The optimal

treatment plan involves discontinuation of the benzodiazepine after 2–3 months. Long-term use of benzodiazepines can present a significant difficulty in getting the patient off the medication.

Mission Statement (2020)

The American Psychological Association's Division 33 on Intellectual and Developmental Disabilities/Autism Spectrum Disorder (IDD/ASD) is a professional organization that has the mission of advancing psychological research, professional education, and clinical services that address the needs and increase the quality of life of individuals with IDD/ASD across the lifespan.

Some of the goals that drive our work include:

- Promoting social justice and inclusivity through our clinical work, research, and education related to IDD/ASD
- Expanding and exchanging knowledge and information about IDD/ASD through research, education, and professional communication
- Enhancing professional development, education, and the quality of professional services that relate to individuals with IDD/ASD
- Building partnerships with individuals with IDD/ASD, their families, and professional organizations that represent them to ensure that multiple perspectives are reflected in research, education, service, and professional development
- Informing legislative and administrative bodies on the importance of psychological, behavioral, and social factors in IDD/ASD and the value of psychology in contributing to the solution

- Strengthening the practice of psychology in IDD/ASD as a distinct professional and scientific entity
- Pursuing the development of high standards in training, practice, and research for psychologists who work in IDD/ASD

Historical Background

Division History

Prior to the formation of Division 33 in 1973, psychologists in the mental retardation field associated with other divisions in APA including Clinical Psychology, Developmental Psychology, School Psychology, Rehabilitation Psychology, Experimental Analysis of Behavior, and also the oldest organization devoted to intellectual and developmental disabilities, the American Association on Mental Deficiency (AAMD), recently renamed the Association on Intellectual and Developmental Disabilities (AAIDD). Edgar A. Doll served 1932–1933 with Frederick Kuhlman as presiding officers of the Clinical Section of APA and as president of AAMD 1934–1935 as he was developing the Vineland Social Maturity Scale (Doll 1935). He also served 1945–1946 as president of the Division of Clinical and Abnormal Psychology (Division 12) after it was formed as a division of APA (Routh 1997).

A number of these psychologists wished that APA had a division devoted to mental retardation, and during the 1970 meeting of the AAMD Region X in Provincetown, Massachusetts, they formed a steering committee to create the division. The members were Allan G. Barclay, Alfred A. Baumeister, Leonard S. Blackman, Lloyd M. Dunn, Norman R. Ellis, Mortimer Garrison, Olivia J. Hooker, Harris Kahn, Henry Leland, Harold Michal-Smith, Murry Morgenstern, William Sloan, and Sue A. Warren. The purpose would be to promote psychology as the “scientist-practitioner” model in the field of mental retardation. The Division on Mental Retardation (Division 33) was officially founded in January 1973 by a vote of the APA Council of Representatives at the annual meeting in 1972.

Marie Skodak Crissey was the first president, and she was followed by Norman R. Ellis and then Henry Leland (Routh 1999).

The Gatlinburg Conference on Theory and Research in Mental Retardation was first held in 1968 as a forum for the presentation of experimental research as well as for informal interactions among participants. For many of these years, it was held annually in Gatlinburg, Tennessee, but recently it has alternated among eastern, western, and southern cities. After the founding of Division 33, the Gatlinburg Conference served as an important scientific forum of the division. The Division 33 executive council often holds its semiannual meeting at the conference. An important resource to both the division and the conference was Theodore Tjossem, the chief of the mental retardation and behavioral disabilities branch of the National Institute of Child Health and Human Development, which supported the institute's Mental Retardation Research Centers program (Routh 1999).

The field of developmental disabilities was characterized by rapid changes in technologies and advances in research during the 1970s and 1980s. In recognition of the breadth of conditions that were recognized to constitute intellectual and developmental disabilities, the division changed its name from the Division on Mental Retardation to the Division on Mental Retardation and Developmental Disabilities in 1988 and to Division on Intellectual and Developmental Disabilities in 2007 and finally, with the emphasis on ASD, to Division on Intellectual and Developmental Disabilities/Autism Spectrum Disorder in 2015. Membership has grown significantly across the six types of membership, which include fellow, member, associate, life, affiliate, and student. Membership increased from 545 members at the end of 2010 to 717 members on December 31, 2019.

The decade of the brain, 1990–1999, ushered in a wealth of new findings on the neurodevelopmental aspects of intellectual and developmental disabilities. During the early 2000s, members were discussing the need to emphasize neurodevelopmental disorders such as ASD in

the division programming. Division President Sara Sparrow of the Yale Child Study Center at Yale University was acutely aware of the lack of representation of ASD researchers and practitioners in APA and Division 33 in particular. At the annual meeting in 2004, a decision was made to emphasize autistic spectrum disorder as one major focus and to reach out to psychologists, graduate students, and other organizations interested in ASD. The outreach has been successful. The number of presentations pertaining to ASD during the division's allotted programming hours at the annual APA meetings has increased to near 50% as has the number of awards for research related to ASD.

Current Knowledge

Landmark Contributions: Autism Spectrum Disorder

There was little empirical evidence that a person with autism could learn or become a productive member of society until 1987 when a multiyear study based on what is now called applied behavior analysis (ABA) was published by O. Ivar Lovaas. The study demonstrated that early intensive behavioral intervention (<4 years old, 40 h/week, including all significant people in all significant environments) for 2 and up to 6 years can produce large gains in most children. Children were able to pass first grade in either a normal or "aphasia classes" (Lovaas 1987). Follow-up at mean age of 13 years showed that 42% were indistinguishable from average children in terms of IQ and adaptive behavior (McEachin et al. 1993). Lovaas helped create the field of applied behavior analysis (ABA). In 1994, he received the division's highest award, the Edgar A. Doll Award, for revolutionizing the treatment of autism.

Claims of "recovery" for some participants were initially greeted skeptically. A number of replications showing strong gains have occurred. However, none of these found as large a gain, though none provided the intensity and duration of the original study (Thompson 2007a). An

overview of five meta-analyses of early intensive behavioral intervention (EIBI) studies (Reichow 2011) concluded that EIBI can produce “large gains in IQ and/or adaptive behavior” for many children and that “the current evidence on effectiveness of EIBI meets the threshold and criteria for the highest level of evidence-based treatments.” EIBI strategies have been evolving from highly structured programs in one-to-one settings to more naturalistic strategies. Pivotal response training, developed by Robert Koegel and Laura Schreibman (former students of Lovaas), and Lynn Koegel, is a naturalistic extension of ABA that targets pivotal aspects of a child’s development including motivation, responsivity to multiple cues, self-management, and social initiations. Pivotal response treatment, when possible, includes teachers and family members to help provide interventions as often as possible in the natural environment (Schreibman and Koegel 2005).

Recently, there has been an increasing emphasis on gene-brain-behavior relationships to provide a more complete understanding of problem behavior (Schroeder et al. 2002). Travis Thompson, past president of Division 33 and recipient of the division’s Edgar A. Doll Award in 2002, proposed that one of the primary tools of ABA, functional analysis of problem behavior, be extended to include biological measures functionally related to the problem behavior (Thompson 2007b). He also addressed the question of why only approximately half of the children treated by EIBI respond well, by pointing to neurophysiological evidence suggesting that practice enhances synaptic growth, which enables communication both within and among brain networks. If individuals lack sufficient neuroplasticity in critical areas, then new synapses may not be formed. He suggested that children with ASD who were responsive to EIBI may have been able to develop synapses in critical brain areas during treatment, whereas those unresponsive were unable to develop synapses in these areas (Thompson 2005, 2007b).

Accurate diagnosis of individuals with ASD is necessary both for research purposes and for determining effective treatment(s). Adaptive behavior

represents what a person typically does rather than the person’s potential and is perhaps the best overall measure to gauge the baseline level of a person’s functioning and subsequently the person’s response to intervention(s). Division 33 members have been active in extending the work of Doll (1935, 1936) to develop the Vineland Adaptive Behavior Scales (Sparrow et al. 1984) and the Vineland Adaptive Behavior Scales-II (Sparrow et al. 2005, 2008), which has become the most widely used measure of adaptive behavior for persons on the autistic spectrum. The 2008 version includes supplemental norms for ASD (Carter et al. 1998). The Vineland Adaptive Behavior Scales, Third Edition was introduced in 2016 (Sparrow et al. 2016). The new version is currently being investigated to help determine concordance with the second edition (Farmer et al. 2020).

Division Publications

Division 33 has one regular publication, the periodic *Psychology in Intellectual and Developmental Disabilities/Autism Spectrum Disorder*. The first issue was in the winter of 1974. The publication appeared irregularly until 1981 when Robert A. Fox began his term as newsletter editor. Subsequently, the newsletter appeared at least two times per year. Contents included division business, articles based on invited addresses, and talks by Division 33 award winners.

Beginning in the early 1990s, officers of Division 33 hoped to generate greater member interest in participating in the affairs of the division by offering space in the newsletters to special interest groups. Regular contributors to subsequent newsletters included an interest group on aging in mental retardation and one related to behavior modification. For a period of time, the newsletter flourished with these additional contributions, and considerable reader interest was generated by the newsletter. John W. Jacobson and James A. Mulick collaborated on frequent columns for the behavior modification interest group. These columns gradually evolved into pointedly humorous critiques and expositions of important issues in developmental disabilities. Several columns were devoted to problems with various definitions and criteria for diagnosing intellectual disability.

Beginning in the late 1990s, quite a few columns were devoted to early intervention and especially early intensive behavioral intervention for young children with ASD. The issue of facilitated communication was also addressed several times in the newsletter, as well as by other actions taken by the division (details later). Finally, the behavior modification interest group column also considered problems associated with the use of aversive motivation in behavior modification. Newsletters from 2000 to the present are available on the division website <http://www.division33.org>.

Division 33 published its own *Manual of Diagnosis and Professional Practice in Mental Retardation* in 1996, edited by Jacobson and Mulick. The peer-reviewed volume was published by APA books and went on to become a best seller for APA. Revenue from the book augmented the division treasury and led to a long period of financial solvency for Division 33.

Major Activities

The division sponsors a series of programs at the annual meeting of the American Psychological Association each year in August. These symposia and other presentations have increasingly included research on ASD. The percentage of the programming has increased from 30% in 2010 to more than 40% in 2019. Moreover, both Student Research Awards in 2019 were focused on ASD.

Division 33 members have always been involved in advocacy on behalf of people with developmental disabilities. At the same time, they have been wary of fads and ephemeral fashions in advocacy that have arisen from time to time in the general community. Many members worked actively in the deinstitutionalization efforts of the 1970s and 1980s. In doing so, they emphasized improvements in treatment approaches including behavioral intervention and assessment. The treatment of severe behavior disorders, in part a result of the deplorable conditions inside institutions and of the absence of services in community settings, led to widespread application of behavioral treatments to normalize their behavior. As treatment procedure evolved, some in the wider field of developmental

disabilities began to grow concerned about the possible detrimental or inappropriate use of behavioral procedures. Pressure to ready former institutional residents for community life was sometimes associated with an emphasis on quick success and less than thoughtful use of powerful and sometimes aversive and restrictive procedures with little concern about alternative approaches. Then too, many in the broad community could imagine that the labor-intensive and sometimes complicated treatment strategies would lead to a loss of autonomy or even mind control over a vulnerable population. This led advocacy groups to criticize the use of “aversive procedures” and to attempt to use regulations and guidelines to control the treatment options that could be used. Division 33 acted to assert a set of guidelines for the limited, appropriate use of aversive and restrictive procedures that were consistent with the scientific literature on behavior change and the need to control severe aggression, self-injury, and destructive behavior that would otherwise deny people with developmental disabilities the ability to live in the community. These guidelines were published in the newsletter and included in the division’s *Manual of Diagnosis and Professional Practice in Mental Retardation* (Jacobson and Mulick 1996), although they were not adopted as official policy of the division or of the American Psychological Association.

The pressure for universal education and normalization of conditions in society for people with developmental disabilities was very intense throughout the last quarter of the twentieth century and remains so at this writing. Inevitably, the extravagant desire for universal inclusion sometimes clashes with the reality of disability in the context of education. Some students have been found to be unable to benefit from all but the most systematic and individualized behavioral educational services and not to be able to participate in traditional teaching approaches in any practical sense. Usually, this is the result of a lack of any viable communication ability on the part of the person with the disability. Into this vacuum of social and family disappointment, unsubstantiated claims were made for the existence of “hidden literacy” that nevertheless could

be induced to emerge with mere manual support of the disabled person's hand or arm over a keyboard or array of letters. As asserted by Syracuse Professor, Douglas Biklen (1990), the manual support procedure was known as "facilitated communication," and credulous teachers, classroom aides, and hopeful parents have been trained in this technique. Unfortunately, a large body of controlled research has established that facilitated communication was, whenever subjected to empirical evaluation, not the product of the person with a disability but rather the often "non-conscious" result of influence by the facilitator (Spitz 1997). Members of Division 33 contributed a critique of facilitated communication which was published in the *American Psychologist* (Jacobson et al. 1995) and lobbied in APA for the passage of resolution discouraging the use of facilitated communication by psychologists for any purpose and cautioning specifically against relying on it as a means of practical communication in any important context. The resolution was adopted as policy of APA by the Council of Representatives in 1994. The full text of the resolution was included in the *Manual of Diagnosis and Professional Practice in Mental Retardation*.

Division Awards

Two Student Research Excellence Awards (annual) are available for students, for proposals submitted for a presentation at the APA annual meeting. During each of the years 2007–2018, at least one of these awards went for a study on ASD. Both awards in 2019 were for studies aimed toward a better understanding of ASD. One study focused on sensory over-responsivity and anxiety, the other on transitioning to adulthood.

The Edgar A. Doll Award (annual) is named in honor of Edgar A. Doll, the research director of the Vineland Training School from 1925 to 1945 where he made profound contributions in the areas of brain injury, electroencephalography (EEG), and adaptive behavior. He is perhaps best known for developing the Vineland Social Maturity Scale (1935), the revised versions of which are generally considered to provide the most useful measure of the impact of intellectual and developmental disabilities (see above). The Doll

award is the division's highest recognition of outstanding scientific contributions to the field of intellectual and developmental disabilities and was first given in 1981 to Samuel A. Kirk.

The John W. Jacobson Award (biannual) acknowledges John W. Jacobson's dedication to critical thinking in the field (see contributions above). The Jacobson Award recognizes meritorious contributions to the field of intellectual and developmental disabilities in an area directly related to behavioral psychology, evidence-based practice, dual diagnosis, or public policy and was first given in 2007 to Richard Foxx.

The Sara S. Sparrow Early Career Research Award (see her contributions above) of Division 33, alternating biannually with the Jacobson Award, honors an early career individual who has made substantial contributions to the understanding of intellectual or developmental disabilities as reflected in his or her published and presented works. The award was first given in 2008 to Luc Lecavalier.

Future Directions

The division will continue to emphasize autistic spectrum disorder (ASD) as a major focus and to reach out to psychologists, graduate students, and other organizations interested in ASD. Programming at the annual meeting will include research aimed toward a better understanding of the genetic, neurophysiological, psychological, and social factors and their interactions that underlie ASD and other intellectual and developmental disabilities.

Ethical treatment has become more of an issue with the emergence of a movement by people with ASD against ABA, some labeling ABA as abuse (Michelle Dawson 2004). The appliedBehaviorAnalysisEdu.org, (n.d.) addresses this issue and states that "The decision-making process needs to be handled on a case-by-case basis with respect to the severity of each individual's condition." The emphasis on treating individuals in their natural environment with many or most caregivers involved in the treatment plan (Schreibman and Koegel 2005) should help minimize those concerns. There appears to be more of an effort to

address the complex issues regarding which stakeholders have ethical-legal authority to weigh in on decision-making.

The division has five special interest groups: behavior modification and technology, dual diagnosis, early intervention, aging and adult development, and making the transition into adulthood. Division members involved pursue research in these areas and contribute to the scientific and professional literature. They participate in forums at professional meetings to present and discuss the latest findings. In particular, members promote and organize symposia at professional meetings. They also advocate in their communities for treatment services for individuals with ASD and other intellectual and developmental disabilities. Members also provide direct treatment services as well as train others to provide these services.

The Division Executive Council has closely monitored the development of the regulations, required by 2010 health-care legislation, that pertain to psychological services for individuals with developmental disabilities, especially ASD. Division members continue to work with the central APA office to inform HHS and state agencies of best practices for the treatment of individual with ASD and to emphasize the need to provide adequate health insurance coverage for these expensive services.

Apgar Score

Susan Hyman

Developmental and Behavioral Pediatrics,
Division Chief Neurodevelopmental and
Behavioral Pediatrics, University of Rochester
Golisano Children's Hospital, Rochester, NY,
USA

Definition

The Apgar score is a numerical score developed by Virginia Apgar, MD, an American anesthesiologist, in 1952 to standardize the description of newborn infant medical stability in the delivery room. A scale from 0 (worst) to 2 (normal) is assigned to the following parameters: heart rate (no heart rate to normal >100 beats per minute), respiratory effort (no respiratory effort to cries and has regular breathing), muscle tone (flaccid to

active motion), reflex irritability (no response to grimace and cry), and skin color (dusky blue to pink). The scores are added up to quantify the infant's status at 1 and 5 min. Infants rarely receive perfect scores of 10 because they typically have bluish-colored fingertips even if they are otherwise pink (1 for color). Lower Apgar scores may reflect neonatal stress, use of maternal anesthetic, and immaturity or prematurity. Apgar scores were designed for use with term infants. Scores of 0–3 at 1 and 5 min indicate neonatal depression and suggest the need for medical attention to help the baby adjust to postnatal conditions. A lower Apgar score at 1 min with a normal range score at 5 min is not typically of concern. Apgar scores are not measures of neonatal asphyxia or necessarily predictive of later neurologic impairment.

Aphasia

Elizabeth R. Eernisse

Department of Language and Literacy, Cardinal
Stritch University, Milwaukee, WI, USA

Short Description or Definition

Aphasia, from the Greek term “aphatos” meaning “without language,” is a disorder caused by

damage to the language areas of the brain. Depending on the type and severity of the damage, deficits may be noted in language comprehension and/or production and can include both the spoken and written modalities. Aphasia most commonly occurs secondary to stroke in which brain cells are deprived of oxygen, resulting in tissue death, but it can also be the result of degenerative disorders or traumatic brain injury. Aphasia can co-occur with other conditions including apraxia and dysarthria which are neurologically based motor disorders that can affect speech output.

Categorization

Historically, aphasia has been classified according to the region of the brain that is affected and the symptoms that are displayed. For example, damage to what is considered “Broca’s area,” the region anterior to the Rolandic fissure, often results in a nonfluent form of aphasia in which comprehension is intact, but articulation and speech output, including syntax, is impaired. A disorder in which syntax and language output are preserved, while comprehension is impaired, is often referred to as Wernicke’s aphasia, due to the frequent damage that is observed in Wernicke’s area within the temporal lobe of the brain. However, as research continues to indicate that there is not necessarily a one-to-one correspondence between region in which brain damage is displayed and the type of symptoms that are experienced, other classification systems have developed.

More recently, types of aphasia have been divided into two categories: fluent and nonfluent aphasias. Fluent aphasias include Wernicke’s aphasia (above) and are characterized by individuals speaking in long sentences that often contain unnecessary words and are devoid of meaning. Comprehension in Wernicke’s aphasia is often impaired as well.

Nonfluent aphasias include Broca’s aphasia (above). In addition, global aphasia is another nonfluent aphasia that is characterized by extensive brain damage and severe communication deficits in both receptive and expressive language.

Epidemiology

The incidence of aphasia is largely unknown, given that it occurs in many types of disorders including cerebrovascular, traumatic, and degenerative disorders. In general, it is estimated that about one million individuals in the USA demonstrate aphasia with approximately 80,000 individuals acquiring this disorder every year (ASHA 2008).

Natural History, Prognostic Factors, and Outcomes

Outcomes for patients with aphasia vary greatly depending on the type and location of brain damage and level of severity of the disorder. Recovery is often more favorable for younger individuals or individuals with less extensive brain damage. In addition, language comprehension skills are often recovered more completely than language production skills. Factors including age of onset, health, education level, and how soon treatment takes place after brain damage have been shown to be predictive of recovery in aphasia.

Clinical Expression and Pathophysiology

Aphasia typically manifests itself as a difficulty in language comprehension, production, or both depending on the type and severity of the condition. Aphasia most commonly occurs secondary to stroke, but it can also be the result of degenerative disorders or traumatic brain injury.

Evaluation and Differential Diagnosis

Aphasia is typically initially diagnosed by a neurologist or other physician who is responsible for the treatment of the patient’s physical and neurological symptoms utilizing case history and observation. Further evaluation by a licensed speech-language pathologist often follows. Evaluation

includes the use of language in both comprehension and production contexts, including reading and writing. Evaluations typically include taking a comprehensive case history, observation of the patient in daily contexts, and formal evaluations of language skills, including naming of objects. Standardized evaluation tools that often are used include the Boston Diagnostic Aphasia Examination (Goodglass et al. 2000), the Boston Naming Test (Kaplan et al. 1983), and the Western Aphasia Battery (Kertesz 2006). Once the individual's profile of language strengths and needs is determined, treatment is initiated.

Treatment

Treatment for aphasia is often multifaceted and is typically individualized based on the patient's profile of strengths and needs. Individuals with aphasia often enroll in formal speech-language therapy to address functional communication in a variety of settings in which they are expected to communicate. Therapy goals are focused on maximizing the individual's ability to communicate effectively with peers and family members, given residual strengths. In addition, computer-assisted treatments are beginning to show promise as supports for individuals with aphasia.

Although some individuals recover completely, individuals with aphasia often experience lifelong deficits. In these cases, family member and patient support groups are often a critical piece of the therapeutic process as the patient and family learn to manage their new situation. The National Institute on Deafness and other Communication Disorders (NIDCD 2011) recommends the use of the following caregiver support strategies:

- Simplify language by using short, uncomplicated sentences.
- Repeat the content words or write down key-words to clarify meaning as needed.
- Maintain a natural conversational manner appropriate for an adult.

- Minimize distractions, such as a loud radio or TV, whenever possible.
- Include the person with aphasia in conversations.
- Ask for and value the opinion of the person with aphasia, especially regarding family matters.
- Encourage any type of communication, whether it is speech, gesture, pointing, or drawing.
- Avoid correcting the person's speech.
- Allow the person plenty of time to talk.
- Help the person become involved outside the home. Seek out support groups such as stroke clubs.

Aphonia

Elizabeth R. Eernisse

Department of Language and Literacy, Cardinal
Stritch University, Milwaukee, WI, USA

Synonyms

[Loss of voice](#)

Short Description or Definition

Aphonia is the complete loss of voice, typically due to an acquired cause such as vocal cord paralysis or damage to the recurrent laryngeal nerve. In aphonia, phonation (i.e., the process by which sounds are produced through the vibration of the vocal folds) is completely impaired, in contrast to dysphonia in which sound production is limited but not completely absent. Individuals with aphonia are only able to whisper when attempting to speak.

Epidemiology

While specific epidemiologic estimates of the incidence of aphonia are rare, generally speaking, approximately 7.5 million people in the United States demonstrate difficulty with vocal use. Voice disorders are more prevalent in individuals working in occupations that are characterized by frequent or intense vocal use.

Natural History, Prognostic Factors, and Outcomes

Some of the known causes of aphonia include laryngeal or thyroid cancer, vocal fold paralysis, nodules or polyps on the vocal folds, vocal abuse, respiratory problems, injury to the laryngeal nerve, surgical removal of the larynx, vocal fold thickening, or, in rare cases, psychogenic causes. Risk for aphonia increases when an individual is exposed to surgery involving the larynx, when an

individual engages in vocally abusive behaviors such as smoking or vocal overuse, or when an individual experiences anxiety. Prognosis for recovery largely depends upon the cause, severity, and nature of the disorder.

Clinical Expression and Pathophysiology

Aphonia manifests itself as a complete loss of voice. Some individuals are able to whisper, while others demonstrate total vocal loss.

Evaluation and Differential Diagnosis

Aphonia is typically diagnosed by medical professionals who specialize in voice disorders such as physicians who specialize in Ear, Nose, & Throat conditions (ENTs), or medically trained speech-language pathologists. Diagnostic procedures typically involve thorough case histories as well as physical examination to determine possible causes. Diagnostic procedures include analyses of vocal fold function including laryngoscopy and videostroboscopy. In the case of the absence of a clear physical cause, psychological evaluations are often recommended.

Treatment

Treatment of aphonia depends upon the nature and severity of the disorder. Treatments can include surgery, counseling for anxiety and related issues that appear to be causing tension that limits vocal fold function, lifestyle changes such as vocal rest, change of occupation, increased hydration, relaxation techniques, and formal voice therapy. Often therapy with a licensed speech-language pathologist is recommended, especially in cases where specific counseling and treatment techniques appear to be beneficial to the patient in terms of recovery of vocal function.

learning of adaptive, constructive behavior and by reducing excessive problem behavior. Within ABA, the behaviors to be changed and descriptions of interventions responsible for changes are explicitly defined and technologically exact, allowing replication of procedures by others. Scientific methods, including objective description, measurement, and experimentation, allow analysis and establishment of functional relationships between interventions and behavior change. It is these interventions that have been come to be known in the public vernacular as ABA.

Historical Background

In his experiments with non-human animals, B.F. Skinner discovered the principle of *operant conditioning*, where consequences following responses result in changes in future behaviors. These principals of behavior and learning provided the foundation of many experimental studies that were eventually extended to humans in the 1950s. With the publication of the *Journal of Applied Behavior Analysis*, these interventions, previously known as behavior modification, and studies formed the basis of what is now known as *applied behavior analysis*. This branch of behavior analysis had as its goal of the improvement socially important behavior in the real world.

In the 1960s, a groundbreaking study was conducted with a 3-year-old child with autism who was at risk for permanently losing vision because he would not wear his glasses (Wolf et al. 1964). He displayed self-destructive tantrums, had sleeping problems, eating problems, and severe deficits in functional communication. Attempts to treat these problems with sedatives, tranquilizers, and restraints were unsuccessful.

Behavioral intervention consisted of shaping of behavior by reinforcing successively longer periods of glasses wearing with small bits of preferred food and of removal of social attention for tantrums. Gains in appropriate speech resulted from presenting clear cues to verbalize and reinforcement of correct responses with small bites of food. What is now known as *discrete trial training* was pioneered in this original effort. Additional

Applied Behavior Analysis (ABA)

Kathleen Dyer
River Street Autism Program at Coltsville,
Capitol Region Education Council/Elms College,
Hartford, CT, USA
Endicott College, Bloomfield, CT, USA

Definition

Applied behavior analysis (ABA) is a science that identifies variables that meaningfully and lawfully influence socially significant behavior in real-world settings. This is done by using principles of behavior to successfully teach and support the

hallmarks of this study were staff and parent training, early intervention, and systematic follow-up to ensure maintenance of treatment gains, as well as teaching of new, socially-appropriate behavior. In addition, the natural setting intervention for children with autism, data collection, and early single-subject methodology became foundational practices of applied behavior analysis.

Excitement from these early studies led to the development of laboratories that focused solely on the treatment of children with autism, with the most notable being the Behavioral Intervention Clinic at the University of California, Los Angeles (UCLA), directed by O.I. Lovaas. Rejecting the earlier notion that autism was a psychopathology caused by poor mothering, the behavioral model focused on treating behavioral deficits and excesses exhibited by the children. These early studies also revealed the deleterious effects of institutional environments and the positive effects of intensive, early, comprehensive treatments that included parent training in community settings.

The results of a 1987 study published by the UCLA laboratory, showing that 47% of 19 children achieved normal intellectual functioning, as well as successful inclusion in school, resulted in controversy regarding the methods employed in the study and the dramatic results that were gained (Lovaas 1987). Many replication studies were conducted following this historical intervention that became known as Early Intensive Behavioral Intervention (EIBI) (e.g., Sallows and Graupner 2005). While the results of the subsequent studies did not reveal the extent of improvement in the 1987 study, positive effects of EIBI were still evidenced, with children showing socially meaningful improvements as a result of behavioral intervention. Researchers and scholars in the scientific community responded to findings with questions regarding the effectiveness of this intervention with children of varying severity levels and with comorbid diagnoses. Many scholars cautioned against a “one-size-fits-all” philosophy when considering EIBI interventions.

A change in terminology occurred when the interventions designed from the science of *applied behavior analysis* began to be commonly

referred to as “ABA.” Common use of the term in the public vernacular referred to one-to-one discrete trial interventions in low-distraction environments, where individual skills were taught using a *massed-trial* approach using high rates of positive reinforcement.

However, scholars and researchers continued to use the science of applied behavioral analysis research, including single-subject designs and socially valid outcomes, to expand the intervention strategies. Interventions were developed to increase the amount of child control in the intervention by incorporating children’s choices and preferences and following the child’s lead in language intervention (Koegel et al. 1999). In addition, researchers discovered that many problem behaviors served a communicative function for valid needs, including the need for attention, the need for assistance, and the need to say, “No”, to unpleasant things. This evolved into functional communication training as a major focus of behavioral intervention, where learners were taught appropriate communication to replace severe problem behavior (Carr and Durand 1985).

In addition to an expansion of treatments, applied behavior analysis treatments expanded to include interventions across the age range, including toddlers, older children, adolescents, and adults, with emphasis on appropriate academic skills in the classroom, vocational skills, and peer socialization. Settings expanded to include entire day and residential treatment facilities devoted to behavioral intervention for learners with autism, inclusion models, applications in public schools, home programs, community settings, and adult education programs. Today, ABA procedures are now being implemented with individuals with autism spectrum disorder (ASD) internationally.

Rationale or Underlying Theory

The ABA model addresses behavior scientifically and views behavior from a functional vantage point. This model sees specific responses as those selected for survival by the function they perform. Behavior is examined objectively and viewed as evolving from people’s histories of

interactions with their environments. Scientific investigation is conducted in the real-world laboratory, and behavior is analyzed to determine systematic relationships between conditions of the environment and resultant behavior.

Goals and Objectives

In ABA interventions, socially-valid behavior-change goals that are beneficial to learners are of primary importance. In autism intervention, goals focus on behavior change in areas of behavioral deficits, including communication, social, and play behavior, and areas of behavioral excess, including repetitive behavior patterns and problem behaviors, such as self-injury, aggression, property destruction, and tantrums. Overall goals focus on building age- and developmentally-appropriate skills to improve independent functioning in home, school, and community settings. Questions to guide goal development include:

- What skills are interfering with the learning process, and how can we decrease them?
- What skills are necessary for the learner to function within school settings?
- What skills are necessary for the learner to be able to transition to a less restrictive setting or classroom?
- What skills are appropriate to the learner's developmental level?
- What appropriate skills are needed to serve the function of problem behavior?
- What skills are needed to develop independent functioning in home, vocational, and community settings?
- What skills are needed to increase the ability for the learner to make informed choices, becoming their own advocates, and controlling their environment in an effort to improve overall quality of life?

Treatment Participants

Treatment procedures developed from the science of ABA have been used with individuals with

ASD across the age range. It is recommended that treatment begin as soon as a child receives a diagnosis, and this can now occur before 2 years of age. When ABA interventions are begun at this early age, it is recommended that it be combined with *developmental approaches* to intervention. The majority of research studies, particularly those evaluating the efficacy of discrete trial interventions, have been conducted with younger children on the autism spectrum. Fewer studies have been conducted with adolescents and even fewer with adults. In addition, procedures documented with individuals with Asperger's disorder are limited to *social narratives*, *video modeling*, and *self-management packages* (see below). Finally, at least one study has found negligible effects of intensive ABA interventions for children with Rett syndrome.

Treatment Procedures

Treatment procedures developed from the science of ABA, heretofore referred to as ABA interventions, have a behavioral emphasis as their foundation. The cornerstone is *differential reinforcement*, where desired behaviors are reinforced, and undesired behavioral excesses are not reinforced. By reinforcing behaviors that are more functional than the problem behavior, inappropriate behaviors are thereby replaced with appropriate behavior. For learners with ASD, ABA interventions are commonly on a continuum of instructor-directed activities in low-distraction, isolated environments to interventions that have a higher degree of shared control between the instructor and learner, with more peers, in naturalistic school, home, and community environments. Descriptions of these interventions are as follows:

- *Discrete trial intervention*: This enhances learning through simplifying and individualizing instruction. Initial treatment often focuses on intense training of small, discrete skills through repeated opportunities to respond to trials. This helps present instruction in a clear

manner with the general format for a training trial as follows:

- The instructor presents a clear cue (instruction or question) to the learner who is attending to the instructor or task at hand.
 - The instructional cue may be followed by a prompt to help the learner to respond if needed.
 - The learner responds correctly or incorrectly to the instructor's cue.
 - The instructor delivers a reinforcer if the response is correct or feedback if it is incorrect, with a statement, such as, "Try again", or "No."
 - There is a brief 1–3-s pause before the next trial begins.
- *Antecedent-based interventions:* These involve the modification of environmental events that occur before a target behavior is produced, with the aim of preventing problem target behaviors and setting the occasion for competing appropriate behaviors. For example, providing a fast instructional pace prevents the occurrence of competing repetitive behavior, and *providing choices of tasks and preferred materials* increases interest level and motivation. Other antecedent interventions include (1) providing cues about schedule changes, (2) providing materials that the learner can engage with to compete with interfering behavior (such as using a squeeze ball while walking to reduce hand flapping), (3) allowing the learner to practice known skills while learning new skills to increase success and motivation, (4) errorless learning, and (5) priming, by exposing the student to aspects of the lesson ahead of time.
 - *Errorless learning/teaching:* The instructor prevents or minimizes learner errors by providing the most assistance necessary for the learner to make the correct responses early in teaching the skill. While assistance is gradually faded, it is provided to prevent incorrect responses throughout teaching.
 - *Modeling:* This procedure involves demonstrating to the learners the targeted behavior for them to imitate. This can be done "in vivo" or with videotaped models. With *video modeling*, learners watch a video of the targeted behavior as a preliminary step in teaching. This technique is commonly used to teach social skills, appropriate academic behavior, and play skills.
 - *Natural language interventions:* Hallmarks of natural language interventions are following the learner's communicative initiations for access to preferred items and activities. The instructor sets up the environment with preferred items and activities, and after the learner indicates a desire for the item, the instructor prompts the learner to use an elaborated and appropriate form of communication. Prompts to communicate are faded over repeated opportunities to communicate requests for the items, such that the preferred item becomes the cue for appropriate communication rather than reliance on external instructor prompts. These interventions have been referred to as *incidental teaching*, *the natural language paradigm*, and *pivotal response training*.
 - *Functional communication training:* When children are using problem behavior to communicate a need to gain something desired or avoid something undesired, appropriate communicative behaviors are taught to replace these problem behaviors. Widely targeted communicative responses include requesting preferred items, attention, a break, or protesting undesired activities or items.
 - *Prompts and prompt fading:* Prompts are extra cues used to effectively guide the learner's response and are faded during the course of treatment. Prompting strategies include:
 - *Fading prompt intensity:* This is done gradually, over a series of successive trials, where progressively less intense stimuli are used to guide the learner to make a correct response.
 - *Least-to-most prompting hierarchies:* Also referred to as a system of *least intrusive prompts*, this provides the learner an opportunity to perform the response on each trial. If the learner does not respond correctly after an instructional cue, the teacher

provides more assistance (e.g., a verbal prompt). If, after a short latency, the learner fails to make the correct response, the instructor provides even more assistance (e.g., a model). This is followed by even more intrusive prompting (e.g., a physical prompt) until a correct response is achieved.

- *Graduated guidance*: This employs prompts of decreasing intrusiveness and is typically used to ensure errorless responding. For example, an instructor teaching a learner to ride a bicycle would begin with full physical prompting and gradually fade to partial physical prompting and then to shadow prompting by keeping his hands close to the learner, as the learner gradually gains physical control over the response.
- *Time delay*: When using a time-delay prompting strategy, the instruction is provided, and after a brief delay (usually a few seconds), the prompt is provided.
- *Script/Script fading*: Verbal statements, in written or audio format, are provided to the learner to repeat in social/communicative situations, such as having a conversation and initiating to a peer. The scripts are faded over teaching sessions.
- *Shaping*: New responses that are not yet in the learner's repertoire are shaped through reinforcement of successive approximations to the targeted response. For example, if a learner were learning to request a preferred toy by pointing, the teacher would first reinforce the child if they reached for the object, and then over successive trials, the child would be required to make a more specific finger-pointing response to gain access to the toy.
- *Task analysis/chaining*: This involves breaking down complex skills that have many steps into their component parts, such as multi-step vocational, self-care, leisure, and independent academic behaviors. Then, each step of the chain is taught individually. Examples of behaviors that are task analyzed and taught through chaining are shoe tying, bed making, and operating a computer.
- *Visual supports*: Visual stimuli are used to aid the individual with ASD to engage in appropriate behavior. These stimuli can include pictures, words, objects, labels, scripts, and visual boundaries. Widely used visual supports include (1) *picture activity schedules*, which provide the steps to engage in a sequence of independent play, vocational, or self-care activities; (2) *visual schedules* which provide the learner with support to independently transition across activities; and (3) *scripts*, which can assist individuals during social exchanges.
- *Picture exchange communication system (PECS)*: Learners are provided with *visual supports* in the form of pictures that are exchanged with a listener during communicative interactions. Communicative skills in the PECS system include (1) spontaneous requesting of items, activities, assistance, and breaks; (2) commenting; (3) building sentence structure; and (4) responding to "What do you want?"
- *Pivotal response training*: Pivotal skills known to affect large areas of learning are the focus of this intervention. Attention, motivation, responding to multiple cues, self-management, and self-initiation are skills that provide the foundation upon which widespread generalization of learning can occur. Characteristics of pivotal response training include using learner interests in the context of play; varied materials and responses; reinforcement of attempts to communicate; shared control; and using natural and direct reinforcers.
- *Self-management*: The individual is taught to independently regulate their own behaviors by setting their own goals, accurately record and monitor their own behavior, and reward themselves for engaging in desired targets.
- *Peer- and sibling-based interventions*: Same-aged peers or siblings can support the learning of the individual with ASD using behavioral strategies. While these have customarily involved social skills training, additional areas of training have involved the implementation of *natural language training*, *discrete trial intervention*, and *picture exchange communication systems*.
- *Parent-implemented interventions*: Parents have been successfully trained to use

behavioral intervention strategies to build appropriate skills and reduce problem behaviors using all the ABA-based procedures delineated in this section.

- *Social narratives*: These describe situations with examples of desired responding and relevant cues to display those behaviors and are often presented in a short-story format with salient pictures. They are used as a precursor to an upcoming event and are often used to teach appropriate social skills and address problem behaviors.
- *Programming for generalization*: Skills are taught using the above-described strategies across persons, places, language cues, and settings, including teachers, parents, and other significant others in school, home, and community settings.

Efficacy Information

Expert panels and task forces have reviewed ABA interventions for individuals with ASD. Criteria for an evidenced-based practice included multiple publications of peer-reviewed, experimentally controlled research in scientific journals with individuals with ASD, across different investigators or research groups. ABA practices have been determined as meeting the stringent criteria developed by the National Professional Development Center on Autism Spectrum Disorders and the National Autism Center's Standards Project. In addition, ABA practices are endorsed by the United States Surgeon General and in reports of the New York Department of Health Early Intervention Program, as well as the Maine Administrators of Services for Children with Disabilities. Additional organizations that endorse ABA as a scientifically proven approach include:

- Autism Speaks
- American Academy of Neurology
- American Academy of Family Pediatrics
- American Academy of Pediatrics
- American Academy of Occupational Therapy Association
- American Psychological Association

- American Speech-Language-Hearing Association
- Society for Developmental and Behavioral Pediatrics
- Autism Society of America
- National Institute of Child Health and Human Development
- National Institute of Mental Health

Outcome Measurement

Socially meaningful, observable behavioral outcomes are the foundation of ABA interventions. Individualized, observable, and measurable target behaviors are continually assessed, with 10 to 40 trials per day as a standard in many ABA programs. Data are collected on the frequency, intensity, duration, and accuracy of targeted behaviors to both identify pretreatment levels of functioning, as well as evaluating response to treatment. Criterion is established at the beginning of treatment to provide clear indicators of mastery of the target behavior, and data-based decisions are made regarding modification of treatment, if necessary. Data outcomes are summarized at regular intervals for evaluation from the client, family, funders, and other stakeholders. Successful outcomes are those where the targeted behavior change has been achieved and that the change has maintained in the presence of natural contingencies, as well as generalized across persons, settings, and other relevant situations where the behavior occurs. In addition, social validity data, interviews, and rating scale data are collected typically from consumers, caregivers and other stakeholders to ensure treatment outcomes are socially significant and appropriate. Finally, assessment from other professionals of overall intellectual and academic functioning, as well as medical status, is recommended.

Qualifications of Treatment Providers

It is recommended that ABA programs are supervised by individuals who have certification by the

Behavior Analyst Certification Board® (BACB®) as a Board Certified Behavior Analyst® (BCBA®). Standards for certification as a BCBA® can be found in the Consumer Information section of www.BACB.com. In addition to certification as a BCBA, many states have now enacted licensure regulations to practicing behavior analysis, with certification as a BCBA as a requirement for licensure in most states. BCBA® certification does not guarantee experience in delivering ABA services to persons with ASD. Thus, additional expertise in delivering ABA services to persons with autism is advised.

Additional training in areas including causes and characteristics of autism, curriculum, assessments, autism-specific intervention, and family concerns is recommended. Please refer to *Applied Behavior Analysis Treatment of Autism Spectrum Disorder: Practice Guidelines for Healthcare Funders and Managers* for a complete review of these recommendations.

Persons who deliver treatments that are developed and supervised by a BACB®-approved provider must have demonstrated competency in following written lesson plans, data collection, and behavior reduction plans using ABA procedures described above. In addition to the BACB credential, the BACB® now provides the Registered Behavior Technician® (RBT®) credential for behavioral technicians who implement direct intervention under the supervision of a BCBA®.

The New England Center for Children,
Southborough, MA, USA

Synonyms

Vocational training

Definition

One method to include individuals with autism in the workplace is through the use of apprenticeships. An apprenticeship involves direct on-the-job training by a qualified individual. This structured training may be supplemented by classroom-based training. Apprenticeship programs typically last for 1–5 years and are concluded based upon completing a pre-specified number of hours, meeting specific job competencies, or a combination of both. Apprenticeships allow individuals with autism to gain job skills in integrated settings while earning an income, which typically increases over time.

Apraxia

Allison Bean Ellawadi
Speech and Hearing Science, The Ohio State
University, Columbus, OH, USA

[Dyspraxia](#)

Short Description or Definition

Apraxia is a neurological motor disorder that impairs an individual's ability to perform voluntary movements in the absence of weakness, paralysis, or neuromuscular slowness (Duffy 1995; Freed 2000; Vinson 2007). Apraxia is subtyped according to the area of impairment and ranges in severity from mild to severe (NINDS n.d.).

Categorization

Apraxia is a neurological motor disorder that is subtyped according to the area of impairment. Some apraxias affect general motor movements, while others affect the speech mechanism. Apraxias that affect general motor movements include limb-kinetic apraxia (impairment in the ability to make fine precise movements with an arm or leg), ideomotor apraxia (impairment in the

ability to make appropriate movements in response to a command), and ideational apraxia (impairment in the ability to coordinate activities with sequential movements, such as dressing). Apraxias specific to the speech mechanism are nonverbal oral apraxia (impairment in the ability to carry out facial movements on command) and apraxia of speech (impairment in coordinating mouth and speech movements to produce speech), also known as verbal apraxia or dyspraxia. Different types of apraxia may occur alone or together (Freed 2000; NINDS n.d.).

There are two types of apraxia of speech, acquired and developmental. Acquired apraxia of speech, or adult apraxia of speech, occurs after neurological insult, such as a stroke (e.g., ASHA 2007; Freed 2000). Developmental apraxia of speech, also known as childhood apraxia of speech, is a developmental motor speech disorder. Both acquired and developmental apraxias of speech are characterized by impaired volitional movements of the speech structures. The core features of acquired apraxia of speech and childhood apraxia of speech overlap. However, because of the significant difference in the time in development at which the disorders manifest themselves, there may be important differences in associated features (Massen 2002; ASHA 2007). This encyclopedia entry focuses mainly on childhood apraxia of speech, also known as developmental apraxia.

Epidemiology

Acquired apraxia of speech arises from neurological insult such as stroke, degenerative disease, trauma, or tumor (Freed 2000). Stroke is the leading cause of apraxia of speech in adults followed by degenerative diseases (Duffy 1995). In contrast, childhood apraxia of speech may occur as the result of unknown causes or in association with complex neurobehavioral disorders of known or unknown origins (e.g., fragile X syndrome). Recent research suggests that childhood apraxia of speech may have a genetic basis (for a review, see ASHA 2007). Little data is

available on the prevalence of acquired apraxia of speech or childhood apraxia of speech. Studies examining population estimates of childhood apraxia of speech are based on clinical referral. Population estimates range from one to two children per thousand to 2.4–4.3% of children referred with speech delay of unknown origin, with a 3:1 male to female ratio (Delaney and Kent 2004 as cited by ASHA 2007; Shriberg et al. 1997).

Natural History, Prognostic Factors, and Outcomes

The developmental course of childhood apraxia of speech is not well documented (Shriberg et al. 1997). The signs and symptoms of childhood apraxia of speech may vary across children and within the same child over time (ASHA 2007). This is further complicated by the finding that children appear to move in and out of the childhood apraxia of speech diagnostic category at different points in development. For example, children initially diagnosed with an articulation disorder may go on to receive a diagnosis of childhood apraxia of speech and vice versa (Hall 1989). Research suggests that children with apraxia of speech make improvements between preschool and school-age in articulating single words and in their overall intelligibility. However, these children continue to have difficulty sequencing multisyllabic words and persistent concomitant language impairments (Lewis et al. 2004).

Clinical Expression and Pathophysiology

Children suspected of having apraxia of speech typically demonstrate deficits in at least one of the following domains: nonspeech motor behaviors, motor speech behaviors, speech sounds and structures, prosody, language, metalinguistic/phonemic awareness, and literacy. Nonspeech motor behavior deficits are characterized by general awkwardness or clumsiness, impaired volitional oral movements, mild delays in oral motor

development, mildly low muscle tone, hyper- or hyposensitivity in the oral area, and oral apraxia. Motor speech deficits are characterized by slow development of speech, reduced phonetic inventory, multiple speech sound errors, reduced percentage of consonants correct, and unintelligibility. Both the nonspeech and motor speech deficits observed in apraxia are also found in other speech sound disorders such as speech delay and dysarthria. Characteristics that appear to be distinctive of childhood apraxia of speech include reduced vowel inventory, vowel errors, inconsistency of articulation errors, increased errors in longer or more complex syllable and word shapes, groping, unusual errors, persistent or frequent regression, differences in performance of automatic versus volitional activities (with volitional activities being more affected), and errors in the ordering of sounds, syllables, morphemes, or even words (for a review, see ASHA 2007).

Syllable and prosody production are also affected in children with apraxia of speech. The atypical prosody observed in individuals with suspected childhood apraxia of speech may be attributed to prolonged sound production and prolonged pauses between sounds, syllables, or words. As a result of these prolongations, the sounds, syllables, and/or words are produced as separate entities. This gives the listener the impression of staccato speech. Other prosodic deficits include reduced variability in pitch or loudness, which result in excessive-equal stress (i.e., all or most syllables in a word receiving prominent stress) during speech production (for a review, see ASHA 2007).

Most children suspected of having apraxia of speech have significant concomitant language deficits. These impairments are often more significant and more persistent than in children with other speech sound disorders (Lewis et al. 2004). Language difficulties include poor phonological awareness (a skill that lies at the foundation of literacy development), difficulty perceiving and producing rhymes, and counting syllables. Other areas of difficulty include deficits in word identification and spelling (Lewis et al. 2004; Marquardt et al. 2002).

Evaluation and Differential Diagnosis

There is currently no definitive diagnostic marker for childhood apraxia of speech, and many of the characteristics of childhood apraxia of speech overlap with other speech sound disorders. Thus, the challenge for both researchers and clinicians is to differentiate childhood apraxia of speech from other speech sound disorders. The characteristics that appear to be distinctive to childhood apraxia of speech include reduced vowel inventory, vowel errors, inconsistency of errors, increased errors in longer or more complex syllable and word shapes, groping, unusual errors, regression, differences in performance of automatic versus volitional activities (with volitional activities being more affected), and errors in sequencing. However, these patterns may also be found in children who do not fit the overall pattern of apraxia of speech. Because apraxia impairs motor coordination, clinicians must first rule out muscle weakness, sensory loss, a comprehension deficit, or incoordination as the underlying cause of the impairment. Currently, the minimum age of diagnosis of childhood apraxia of speech ranges from under 2 years of age to under 4 years of age (for a review, see ASHA 2007).

Standardized tests that focus on nonverbal oral motor and/or motor speech performance that may be used to diagnose apraxia include the Apraxia Profile Preschool and School-Age Versions (Hickman 1997), the Kaufman Speech Praxis Test for Children (Kaufman 1995), the Oral Speech Mechanism Screening Examination, Third Edition (St. Louis and Ruscello 2000), Screening Test for Developmental Apraxia of Speech – Second Edition (Blakely 2001), the Verbal Dyspraxia Profile (Jelm 2001), and the Verbal Motor Production Assessment for Children (Hayden and Square 1999). While these tests may assist in diagnosis, they lack normative data and behavioral standards to use in test interpretation and clear behavioral standards on which to base treatment decisions (McCauley and Strand 2008).

Differential diagnosis of childhood apraxia of speech may also include examination of non-speech motor behaviors. Children with apraxia

of speech are more likely to demonstrate general awkwardness or clumsiness, impaired volitional oral movements, mild delays in oral motor development, mildly low muscle tone, hyper- or hypo-sensitivity in the oral area, and oral apraxia (Davis et al. 1998; McCabe et al. 1998; Shriberg et al. 1997). However, many of these motor behaviors are characteristic of dysarthria. In addition, clinicians may use the sequential motion rate task, conversational speech and reading, and repeating words of increasing length to examine motor speech behaviors during diagnostic evaluations (Freed 2000). The sequential motion rate task is one of the most sensitive assessments for differentiating apraxia of speech from other motor disorders (e.g., Davis et al. 1998; Freed 2000; Nijland et al. 2002).

Although there is not currently a validated list of diagnostic features that may be used to differentiate apraxia of speech from other speech sound disorders, three features are consistent with a deficit in the planning and execution of motor movements. These features are (1) inconsistent errors on consonants and vowels in repeated production of syllables or words, (2) lengthened and disrupted coarticulatory transitions between sounds and syllables, and (3) inappropriate prosody (ASHA 2007).

Treatment

There have been few treatment studies of apraxia of speech. Of the treatment studies conducted, none met the highest level of evidence for treatment efficacy (ASHA 2007; Pannbacker 1998). To date, management of childhood apraxia of speech is similar to that of dysarthria and other articulation disorders. Treatment is most often focused on improving speech production. Basic approaches to treating apraxia of speech include (1) linguistic approaches, (2) motor-programming approaches, (3) linguistic-motor programming combinations, and (4) treatments with specific sensory and gestural cueing techniques. Linguistic approaches focus on teaching the child the sounds and the rules regarding sound sequences and sound use. Motor-programming techniques

use principles of motor learning to teach children to acquire the skills needed to make sounds and sequences of sounds accurately and consistently. Other approaches combine linguistic and motor-programming intervention strategies. Finally, there are programs that involve the child's senses such as vision, touch, as well as being touched, to help cue the child about some aspect of the speech sound he or she is attempting to make (Hall 2000; ASHA 2007). For children with significantly reduced intelligibility, treatment goals may focus on facilitating overall communication through the use of Augmentative and Alternative Communication (ASHA 2007).

Arab Views on Autism

Ahmad Hassan

Department of Neuroscience, Yale University
School of Medicine, New Haven, CT, USA

Historical Background

Autism spectrum disorder (ASD) is a neurodevelopmental disorder, mainly presenting with impairments in communication, distinct patterns of social interaction, and restricted or repetitive patterns of behavior (American Psychiatric Association). ASD includes autistic disorder, Asperger syndrome, and pervasive developmental disorder not otherwise specified (PDD-NOS). The symptoms of ASD typically manifest by the age of 3 and persist throughout one's life. However, the condition is commonly missed and not diagnosed until much later in the child's life, especially if the child's symptoms are mild to moderate in severity. Research into ASD has increased dramatically over the past few decades, but unfortunately, most of this research has been limited to affluent, English-speaking nations (Sharpe et al. 2011).

The Arab world consists of 22 member nations in North Africa and the Middle East. These nations include Algeria, Bahrain, the Comoros Islands, Djibouti, Egypt, Iraq, Jordan, Kuwait, Lebanon, Libya, Morocco, Mauritania, Oman, Palestine, Qatar, Saudi Arabia, Somalia, Sudan, Syria, Tunisia, the United Arab Emirates, and Yemen. The population of the Arab world exceeds 400 million, with a diversity of religious, ethnic, and linguistic communities. While the majority of people in the Arab world adhere to Islam and speak some dialect of Arabic, there are various ethno-religious communities which may speak an indigenous language other than Arabic and practice a religion other than Islam.

Historically, children throughout the Arab world who began to display symptoms of autism, such as repetitive behavior and poor social skills, were thought to have been affected by black magic or the "evil eye" and were shunned from society. In recent years, however, pediatricians in

these countries have begun to recognize the symptoms of autism, and countless cases which would previously go unreported are now being diagnosed early enough to allow for successful intervention. ASD research is a very new field in the Arab world (Hussein and Taha 2013).

Organizations such as The Egyptian Autistic Society are being established in order to increase awareness among doctors and parents so as to assist in early diagnosis and treatment of autism (Mendoza 2010). The Autism Research and Treatment (ART) Center at the King Saud University in Saudi Arabia is the first institution in the region to carry out basic research on autism.

The prevalence of ASD worldwide is estimated to be 1 case per 160 children (World Health Organization 2019). However, the vast majority of prevalence studies reviewed by Fombonne (2005, 2009) and Williams (Williams et al. 2006) have been performed in Western nations or affluent Asian nations such as Japan. As such, there is limited research concerning the diagnosis of children with ASD in less affluent, non-Western nations where services and programs for children with ASD are less available. This lack of research has led some writers to make the unwarranted assumption that autism is rare in non-Western cultures (Sanua 1984; Zhang et al. 2006). Available data suggests the prevalence of ASD to be 1.4, 29, and 59 per 10,000 children in Oman (Al-Farsi et al. 2011), the United Arab Emirates (Eapen et al. 2007), and Saudi Arabia (Aljarallah et al. 2006), respectively. The observed lower incidence of ASD in Arab nations in comparison to Western nations is likely due in part to the lack of specialists available in the Arab region to properly diagnose ASD (Mostafa 2011).

While much progress has been made in the past couple of decades in regard to autism research, diagnosis, and treatment in the Arab world, there is still much progress that needs to be made, particularly in autism research. Many experts argue that most of the current research and treatments for autism have been made primarily for an Anglo-Saxon population and thus may not be relevant to Arabs (Sharpe et al. 2011). It is clear that in order to properly address autism in the Arab world, a concerted effort must be

implemented involving government support to research institutions and families, as well as creating campaigns to raise awareness and reduce stigma. Not long ago, many Arab parents would have refused to enroll their child in a school with another autistic child. Although attitudes have now changed, it is not uncommon for parents to hide their autistic child from society due to feelings of shame and embarrassment.

Overview of Current Research

In a review study conducted by Alnemary et al. which examined all published ASD research before January 2014, it was found that autism research was conducted in 13 countries (Alnemary et al. 2017). The majority of the studies were conducted in Saudi Arabia, followed by Egypt and Oman. The majority of the publications addressed the biological aspects of ASD, while the vast minority focused on treatments and interventions. The majority of research areas have begun to show gradual growth over the past few years. Additionally, the majority of ASD publications produced in Arab countries were funded by governmental agencies rather than private organizations. A total of 142 publications were identified from 1992 to January 2014, with a dramatic increase in the number of ASD publications beginning in 2008.

However, while much progress is being made, ASD research in the Arab world remains very limited. There are several factors that may be contributing to the lack of research being conducted. Arab governments and organizations do not prioritize funding for mental health and related fields, putting a constraint on ASD research (Jaalouk et al. 2012). Additionally, many Arab researchers are not able to submit their research to international journals due to language barriers. The majority of publications from the Arab world are written in Arabic, English, or French, and only those written in English are included in international databases (Sarhan 2012).

Another review study analyzing ASD research in Arab countries from the years 1992 to 2012 found that although the majority of identified

papers were published after 2008, autism research is not yet a priority in Arab countries (Hussein and Taha 2013). In accordance with the previous study, it was found that the majority of autism research in Arab countries was concerned with the etiology of the disorder as opposed to treatments or services. This may be due to the fact that medical fields in the Arab world are far more advanced than rehabilitation and educational fields. Furthermore, the majority of etiological studies are concerned with autoimmune and biochemical markers of ASD rather than imaging and genetics. This is most likely due to the lower cost of these methods and the lack of funding available to researchers. Additionally, etiology studies produced in the Arab world do not differ from those produced in Western countries, which, in accordance with previous research conducted by Bristol et al., suggests that no ethnic or environmental factors have been proven to cause autism (Bristol et al. 1996).

The few genetic studies that have been published either have a very limited sample size or are case reports. However, due to Arab culture being characterized by a relatively high amount of consanguineous marriages, there has recently been a growing level interest in genetic research. According to a genetic study conducted in 2009, it was found that one-third of a cohort of Saudi Arabian children with autism had a history of consanguinity (Al-Salehi et al. 2009). In the Arab world, most consanguineous marriages are between first cousins, with the practice being much more prevalent in rural areas. They may also be more prevalent in some countries over others, comprising about 34–80% of all marriages in Saudi Arabia depending on the location. While these findings do not suggest a direct link between consanguinity and autism in Arab countries, the higher incidence of autism among Saudi Arabian families make them ideal candidates for screening studies for genetic variations. An example of this can be seen in a 2008 study in which 88 families with consanguineous marriages and a high incidence of autism were recruited from several countries, including Oman, Saudi Arabia, Jordan, and Kuwait. The DNA of family members was compared in order to identify recessive mutations.

Large chunks of missing DNA which followed the recessive rule was identified in some families, and while the missing regions differed among families, they affected at least six genes that are known to play a role in the development of ASD (Neergaard 2008).

In a 2014 review conducted by Salhia et al., the results of several case-control studies conducted in Bahrain, Saudi Arabia, or Oman were analyzed. The risk factors investigated in these studies included suboptimal breastfeeding, lead exposure, serum osteopontin, maternal and paternal age, cesarean section, and prenatal complications. A lack of colostrum intake and delayed breastfeeding were associated with a higher risk of ASD (Salhia et al. 2014). Additionally, exclusive and prolonged breastfeeding – defined as 24 months or longer – was associated with a lower risk of developing ASD. Higher levels of lead and osteopontin were found in ASD patients, and the disorder was more prevalent among children of mothers who had delivered via cesarean section or experienced antenatal complications.

Additionally, it was found that the levels of several biomarkers were altered in autistic patients compared to healthy controls. Biomarkers that were significantly elevated in autistic patients include lipid peroxidation (Al-Gadani et al. 2009), glutathione peroxidase (Al-Mosalem et al. 2009), superoxide dismutase, sodium-potassium adenosine triphosphatase (Al-Farsi et al. 2012), lactate, saturated fatty acids (El-Ansary et al. 2011), and homocysteine. Biomarkers which were found in lower levels among autistic patients include vitamin E (Al-Gadani et al. 2009), glutathione, folate, vitamin B12 (Ali et al. 2011), and some polyunsaturated acids. Autistic patients also had elevated levels of serum osteopontin, and the levels were positively correlated to the severity of autism (Salhia et al. 2014). The majority of current ASD population studies conducted in Arab countries have several limitations, such as small sample sizes and nonrepresentative populations due to sampling from pediatric wards. Additionally, the majority of ASD research in the Arab world originates from three countries: Saudi Arabia, Egypt, and Oman. Consequently, very little conclusions

or observations may be drawn concerning the Arab world in general.

Future Directions

Although factors such as consanguinity, multiparity, and closely spaced pregnancies are common in the Arab world and would provide for excellent population to study the genetic components of the disorder, there is currently a lack of research into the etiology of ASD in Arab countries. Additionally, research concerning dietary habits and drug usage is almost nonexistent. Research into treatments and services is lacking to an even greater extent, the result of which can be seen in Arab society. There are currently some efforts being done in order to identify autistic symptoms among children in psychiatric wards. The few options available to parents of autistic children are generally very costly and present a large financial burden on the family, and research into the economics of autism in the Arab world is strongly needed.

Furthermore, while general views on autism in Arab societies are slowly changing, there remains much progress to be made in terms of raising awareness and informing the public. It is not uncommon for parents to ignore early symptoms of autism or to hide their children from society due to feelings of shame or not being informed of the options available to them. Raising awareness among parents may allow for early diagnosis and intervention of autistic children. It seems that the most obvious and necessary steps to be taken in the near future involve government funding of research institutions and development of programs specifically geared toward autism diagnosis and intervention.

Argentina and Autism

Mario C. Petersen

Child Development and Rehabilitation Center,
Oregon Health Science University, Eugene,
OR, USA

Historical Background

The recognition of autism in Argentina follows, by a few years, the recognition of ASD in Europe and the USA. In general, since then, Argentine physicians and other professionals have been using the DSM classification system (APA 1980).

A few studies by Argentine researchers give an idea about the prevalence of ASD. Lejarraga et al. (2008) conducted developmental screening in a large sample ($n = 839$) of apparently healthy children of 0–5 years of age, in the Municipality of San Isidro, Province of Buenos Aires. In this study, the authors found 11 children with ASD, which indicates a prevalence of 13/1000 (1 in 76 children). Another prospective study was done in 2014 in children of the Province of Santa Fe by Dr. Francisco Astorino and his collaborators (personal communication). The authors of this study found a prevalence of 1/128 in children between 18 and 36 months. No information is available about the prevalence of autism in older children in Argentina.

It is important to understand and acknowledge the strong influence of psychoanalysis among psychologists and psychiatrists in Argentina. Because psychoanalysis puts emphasis on the subjective experiences of the patients, and does not use any systematic classification, it makes it impossible to generate accurate data on prevalence of ASD, or produce replicable descriptions of the treatments.

Legal Issues, Mandates for Service

Until 1970, most Argentine children with disabilities received their grade education in so-called schools for special education (*Escuelas de*

Educación Especial). The process of integrating students with special needs into the regular public school system started in the 1960s, first with integration of children with hearing and blindness disabilities. In the 1970s, the so-called schools for special recovery (*Escuelas de Recuperación*) were intended to serve children with minor difficulties, referred to such schools by professionals in the public school system. In 2008, the country adhered to the International Convention on Disabled Persons; although, the effort to achieve inclusion of students with autism in the Argentine system of public education is progressing slowly.

In the mid-1980s, it was a remarkable increase in work towards the integration of people with developmental disabilities in Argentina. A new presidential administration created the National Advisory Commission for the Integration of Persons with Disabilities in 1987, to provide a nation-wide platform for the coordination of different actions and proposals to achieve greater social integration of people with disabilities. In 1988, the Ministry of Education and Culture of the Nation launched its National Integration Plan. As a consequence of this renewed focus, many jurisdictions began to engage in school integration projects in those years, mostly supported by special education boards.

The National Education Law of 2006 (Argentine Law 26.026) established the right to inclusive school education throughout the country at all educational levels and modalities, to ensure the integration of the students with disabilities, according to each person's potential.

In 2005, the government of the City of Buenos Aires approved a Resolution (Buenos Aires City Law 650/2005) for people with disabilities that mandated early diagnosis and early therapeutic intervention, aiming at reducing the incidence of autism and severe communication disorders. This resolution also mandated a survey of these disorders, and highlighted the need for an increase in identification, and appropriate medical care of autism and severe communication disorders.

In 2014, the National Congress passed Law 27.043 on the "Comprehensive and Interdisciplinary Approach of Persons Who Have Autism Spectrum Disorders." This law established as goals of

national interest all actions conducive to the following: (a) a comprehensive and interdisciplinary approach to people with Autistic Spectrum Disorders (ASD); (b) clinical and epidemiological research; (c) professional training in early detection, diagnosis, treatment, and research; and (d) dissemination and access to benefits for persons who have Autism Spectrum Disorders. Several, but not all, of the country's provinces have adhered to the national law, or have produced similar legislation.

The treatment of these topics generated a public debate around systematic research on diagnostic classifications, the effects of "labeling" when using a diagnosis, and the so-called "pathologization" of children, as well as the appropriate types of early intervention for each child.

Overview of Current Treatments and Centers

Medical Treatment: In Argentina, the overall health-care system is split between four layers of different but often overlapping systems. The country has a public health system, with public health centers and hospitals providing care that is free, or almost free of cost to the patients. These hospital and community health centers are funded by the federal administration, and/or depend on funding provided by provincial and municipal governments. These institutions deliver services to the largest segment of the population. Another layer of health-care services is delivered by social services (*Obras Sociales*) organized and funded by various workers' unions (*Sindicatos*). Most Argentine employers and employees would regularly contribute to these organizations. The quality and volume of health care provided by social services administered by workers' unions is in direct relationship with the number of workers contributing a portion of their salaries to the unions. Some *Obras Sociales* have large hospitals in Buenos Aires, and in other cities. Yet another layer of health care is delivered by private HMO (*organizaciones prepagas para el cuidado de la salud*). People buy a membership, and pay a

monthly fee to a HMO to receive a certain level of health care from professionals affiliated to the organization. Some of these HMOs own large clinics and hospitals in many regions of the country. The fourth layer of health care in the Argentine system is found in some private local clinics and hospitals, and also private individual health professionals across the country. With such web of providers, which often overlap in the most populated areas, it is difficult to evaluate current medical treatments for autism.

Treatment options vary greatly according to region of the country, and type of health insurance coverage. A fair assessment of the situation would indicate that treatment options for autism depend on the qualifications of the centers, and the competence of the professionals delivering such care.

Across the country, many relatively small private interdisciplinary centers deliver care to children with autism. Most of these centers offer a combination of multiple treatments, and the number of professionals using evidence-based therapies in these interdisciplinary centers seems to be increasing. The professionals' combined form of treatments could include therapies such as counseling, speech therapy, occupational therapy, psychomotricity, *psicopedagogía* (psychology of learning), music therapy, and others. Most interdisciplinary clinics include a physician, usually a child neurologist or child psychiatrist. The counseling received by the children is often based on psychoanalysis (Barcala et al. 2003).

Across the country, an increase in public awareness on the need for early detection of autism is evident; see Ministerio de Salud de la Provincia de Buenos Aires, and Rattazzi (2014). Among professionals, there is also increased emphasis in the use of evidence-based treatments like Denver, SCERTS, TEACCH, floor time, etc. For details, see Cadaveira and Waisburg (2014), García Coto (2001), and Valdez (2016).

Barcala and collaborators (2003) conducted a study in Buenos Aires aiming at obtaining an estimate of accessibility to services for children of autism in the public health system in the city. The authors could not obtain information from all Municipal Hospitals due to insufficient systematization, lack of electronic records, and also

because some health care providers reported that they employed psychoanalytical frameworks which precluded them from submitting detailed quantifiable data.

Another comprehensive study by Barcala et al. (2006) presented an excellent picture of the mental health services offered in public hospitals in Buenos Aires. The authors surveyed all the pediatric mental health services (*Servicios de Psicopatología Infantil*) in the city. Although they were unable to obtain the actual number of children with ASD served in those public hospitals, their study included descriptions of the treatment offered in two psychiatric hospitals with specialized treatments. The authors found that among 32 hospitals, only 9 provided treatment for ASD. Most hospitals offered individual therapy delivered by psychologists, many offered treatments delivered by *psicopedagogas* (professionals specialized in psychology of learning), while a few treatments were done by occupational therapists. Only two of the hospitals in this study had child psychiatrists on staff, providing pharmacological treatment.

In 2006, the theoretical framework most often employed by the staff at Mental Health Centers in public Hospitals in Buenos Aires was psychoanalysis (Barcala et al. 2006). Although, a recent review of the number of centers and academic courses that include ABA and other developmental/educational approaches (Denver, TEACH, etc.) indicates an increase in the use of evidence-based treatments in Argentina.

Overview of Research Directions

Currently, it appears that the country does not have an institutional research agenda for ASD. A review of existing research supported by the National Council for Scientific and Technical Research (CONICET), the main public-funded research organization in the country, indicates that many individual projects are targeting basic research on autism; however, apparently there are no programs or established research groups focused on autism. Some clinical studies on autism by individual scientists are also supported by CONICET.

Overview of Training

Ongoing training of providers (teachers, health care professionals, and others): Some universities are beginning to offer postgraduate education on ASD. Currently, the most relevant academic program in Autism and Asperger Syndrome is a postgraduate program offered by Universidad Católica Argentina (UCA). This program, directed by Drs. Víctor Ruggieri and Daniel Valdéz, presents content supported by evidence-based science. Also, Facultad Latinoamericana de Ciencias Sociales (FLACSO), another major university in Argentina, offers an online postgraduate course on practices for education and inclusion of children with ASD.

A review of the curricula offered in Psychology Departments at several universities across the country indicated that psychoanalysis continues to be the most commonly taught theory; although many more syllabi by faculty in Argentine universities now include behavioral and evidence-based approaches for the treatment of ASD.

ASD is part of the curricula in medical residencies in child psychiatry, child neurology, and neuropsychiatry at several universities. However, ASD is not included in the curricula for most pediatric residencies. While most pediatric residents would receive a few lectures on ASD, few of these residents would obtain adequate training for ASD detection, let alone treatment of children with ASD. Lessons on autism are taught in most of the Health Allied Schools, like those offering academic training on occupational therapy, physical therapy, speech therapy, and educational psychology; however, autism rarely appears as the main subject in a course.

Social Policy and Current Controversies

One important controversy in Argentina is found in concerns of parents and professionals regarding the classification of behavioral/mental conditions, and pervasive effects of labeling on the individuals. Labeling manifests conflict between accepting the

child differences as his/her way of being and the attempt to “cure” or make the child as “normal.”

Most of the formal education for children with special needs continues to be segregated in schools for Special Education. Since relevant legislation passed in 2014, there is major push for achieving greater inclusion of children with ASD in public and private schools. Nevertheless, some parents continue to have concerns about the extent to which the trend would mean a genuine move towards inclusion, and wonder about the possibility of ending up with an actual reduction of services.

In sum, the current diagnosis of autism in Argentina shows increase in awareness and decrease in stigmatization, mainly thanks to the efforts of several parents’ organizations and the effects of their public role in educating the community (see, for example, associations such as TGD padres, <http://tgd-padres.com.ar>; Programa Argentino para Niños, Adolescentes y Adultos con Condiciones del Espectro Autista (PANAACEA) <http://www.panaacea.org/>; and Asociación Argentina de Padres de Autistas <http://apadea.org.ar/>).

Definition

Aripiprazole is a prescription drug in the family of atypical antipsychotics initially FDA-approved for medical use in the year 2002 with the chemical formula $C_{23}H_{27}Cl_2N_3O_2$ (Fig. 1). This compound is a partial agonist of the dopamine₂ (D₂) receptor and the serotonin type 1A (5-HT_{1A}) receptor and is an antagonist of the serotonin type 2A (5-HT_{2A})

receptor. This drug is mostly metabolized by the enzymes CYP2D6 and CYP3A4 of cytochrome P450. Oral formulations in solution, tablet, and rapidly dissolving forms are FDA-approved for the treatment of schizophrenia in adolescents and adults; the acute treatment of manic and mixed episodes in pediatric patients ages 10 years and older and adults with bipolar I disorder, as an adjunct to lithium or valproate; the treatment of major depressive disorder in adults as an adjunctive treatment; and the treatment of irritability in pediatric patients ages 6–17 years with autistic disorder. A short-acting injectable form is FDA-approved for the acute treatment of agitation in adults with schizophrenia or bipolar I disorder. A long-acting injectable form is FDA-approved for the treatment of schizophrenia in adults. Observed side effects include weight gain, nausea, akathisia, headache, insomnia, agitation, anxiety, and mild transient somnolence.

ARX

Definition

The Aristaless-related homeobox gene on the X chromosome produces a homeodomain transcription factor that, by regulating numerous genes, is crucial for many processes during embryonic development, especially the proliferation and migration of neurons. *ARX* is expressed in forebrain interneurons that release the inhibitory neurotransmitter gamma-aminobutyric acid (GABA).

Mutations in *ARX* can run in families or occur sporadically. These mutations cause a range of X-linked developmental disorders that include lissencephaly (“smooth brain”), agenesis of the

Arlington Central School District v. Murphy 2006 (IDEA Not Authorizing Expert Evaluations)

Jonathan Sliva
Quinnipiac University School of Law, Hamden,
CT, USA

Definition

Arlington Central School District v. Murphy
Arlington Central School District (ACSD) v. Murphy concerned parents’ ability to recover costs associated with a successful claim against a local or state educational agency under fee-shifting provisions in the Individuals with Disabilities Act (IDEA). The United States Supreme Court held that expert witness fees were not “costs” as provided for in the act.

Implications for Parents and Professionals Involved in IDEA Actions

The IDEA provides a fee-shifting provision to allow parents prevailing in actions under the Act to recover their costs associated with the litigation. Following *ACSD v. Murphy*, expenses associated with services provided by experts do not fall within the provisions of the act and thus were not recoverable by parents. Allowable costs identified by the Supreme Court as being provided for in IDEA are shown below.

Authorized by 20 U.S.C. 1415(i)(3) (B) (IDEA)	
	Attorney’s fees
Authorized by 28 U.S.C. 1920	
	Fees of the clerk and marshal
	Fees of the court reporter for all or any part of the stenographic transcript necessarily obtained for use in the case
	Fees and disbursements for printing and witnesses
	Docket fees under section 1923 of title 28

(continued)

	Compensation of court-appointed experts (limited to \$40 per diem plus travel expenses under 28 U.S.C. 1821), compensation of interpreters, and salaries, fees, expenses, and costs of special interpretation services under section 1828 of title 28
	Fees for exemplification and copies of papers necessarily obtained for use in the case

Current and Future

On March 17, 2011, in direct response to the Supreme Court’s ruling in *ACSD v. Murphy*, Senator Tom Harkin (D-IA), the Chairman of the Health, Education, Labor, and Pensions Committee; Senator Barbara Mikulski (D-MD); and Senator Bernie Sanders (I-VT) introduced to the Senate the IDEA Fairness Restoration Act, and Congressmen Chris Van Hollen (D-MD 8) and Pete Sessions (R-TX 32) introduced an identical bill in the House of Representatives. This act would amend IDEA’s fee-shifting provision so that “the term ‘attorneys’ fees’ shall include the fees of expert witnesses, including the reasonable costs of any test or evaluation necessary for the preparation of the parent or guardian’s case in the action or proceeding.” The bill is similar to ones that have been introduced in the past two Congresses but which never made it out of committee. As of May, 2011, the bill remains in committee in both the Senate and House of Representatives.

Arousal

Shantel E. Meek and Laudan B. Jahromi
School of Social and Family Dynamics, Arizona
State University, Tempe, AZ, USA

Definition

Arousal is defined as a physiological preparedness to perceive and react to environmental stimuli and is produced by the activation of the sympathetic branch of the autonomic nervous system. An arousal response may be identified through increased heart rate, increased blood pressure, increased sweat gland activity, and dilation of the pupils (Romanczyk and Gillis 2006), and can be indicative of a variety of emotions such as fear, anxiety, excitement, or feelings of competitiveness (Romanczyk and Gillis 2006). Typically, a moderate amount of arousal is optimal for learning (Baron et al. 2006).

Historical Background

An individual's state of arousal can provide valuable insight about a variety of socially significant indicators such as anxiety levels, ability to recognize and react to fearful or stressful situations, and the ability to identify and regulate emotions. Each of these skills is crucial to social functioning and to forming meaningful relationships throughout life. A more in-depth understanding of the history and current state of the arousal literature, as well as a review of typical and atypical demonstrations of arousal, will illustrate the critical role it plays in autism research and the important contributions it can make to interventions. Since the 1960s, numerous studies have measured arousal

in individuals with autism using a variety of different measures. Initially, three main hypotheses explaining arousal dysfunction were studied: hyperarousal, hypoarousal, and difficulties with arousal modulation. Hutt et al. (1965, 1966, 1968) found evidence of hyperarousal which contributed to the hypothesis that individuals with autism are chronically overly aroused and that they regulate their arousal through stereotypical, repetitive motor behaviors. Other studies similarly found that individuals with autism are overly aroused in response to social and nonsocial stimuli and, especially, in response to novel stimuli when compared with typical individuals and individuals with other developmental disabilities (Hermelin and O'Connor 1968; James and Barry 1980). In contrast to the hyperarousal hypothesis, other early investigators found evidence of hypoarousal, that is, chronic underarousal in individuals with autism when compared to typically developing individuals (DesLauriers and Carlson 1969). Early proponents of this hypothesis suggested that individuals with autism engage in stereotypical, repetitive motor behaviors to increase sensory stimulation. Still, others found evidence of fluctuations between both hyper- and hypoarousal dependent on the environment, stimuli, and developmental level of the individuals (Hermelin and O'Connor 1970; Ornitz and Ritvo 1968), thereby forming the hypothesis that individuals with autism experience difficulties in modulating arousal in general, whether hypo or hyper. The varied results noted are likely due to a host of limitations including inconsistencies with terminology and diagnosis identification; most early studies were published prior to the publication of the DSM III-R which more clearly outlined the criterion for an autism diagnosis. This limitation causes uncertainty in the actual diagnosis of participants studied. In addition, the early measurement tools used to measure physiological functioning were likely uncomfortable and may have caused heightened anxiety and arousal for participants. Finally, many studies did not collect baseline data making it difficult to determine resting states of arousal and actual fluctuation, hyper, or hypo states (Goodwin et al. 2006).

Current Knowledge

Technological advances and continued research have provided investigators with the tools to study arousal more uniformly. Currently, heart rate, blood pressure, and skin conductance tests are the most common types of physiological arousal tests studied. Despite the use of more uniform measures, discrepancies in results remain, even within tests. As with early research, more recent studies continue to find that individuals with autism demonstrate elevated levels of physiological arousal (Bellini 2006; Goodwin et al. 2006). One important study found that while individuals with autism were less reactive (i.e., hypoaroused) to environmental stressors than typically developing controls, on average, the autism group demonstrated higher heart rate during baseline and in stressful situations. Interestingly, however, the autism group displayed nearly 50% less variance in heart rate between baseline and stressful situations when compared to the control group (Goodwin et al.). Other studies have found that individuals with autism experienced less arousal than typical individuals when viewing sad or fearful stimuli but more arousal when viewing neutral stimuli (Bolte et al. 2008). Combined, this research may indicate that individuals with autism are chronically hyperaroused or that they experience more arousal than typical individuals in testing situations but demonstrate less arousal during stressful, sad, or fearful situations. Still, other recent work has found no significant group differences in arousal levels between individuals with autism and typical individuals (Ceponiene et al. 2003; Kemner et al. 2002). Inconsistent results may be due to the developmental level of the individuals studied (Dawson and Lewy 1989) and the variability seen within individuals with autism (Zahn 1986), in combination with differences in the measures of arousal (e.g., heart rate, skin conductance).

While much of the discussion in early arousal research was focused on the relations between arousal and stereotypical repetitive motor behaviors, recently, there has been increased discourse regarding the relation between arousal, social

anxiety, and social functioning in individuals with autism. Bellini (2006) recently proposed the developmental pathways model to explain the role of arousal in social anxiety in individuals with autism. Specifically, the model suggests that social anxiety is indirectly the product of temperament, of which physiological hyperarousal is intricately related. Individuals with a temperament marked by increased physiological arousal may withdraw socially in order to prevent overarousal; this social withdrawal may then lead to social skills deficits. Bellini's work is founded in previous work that indicates that individuals that demonstrate hyperarousal levels may be more likely to develop social anxiety in response to negative peer interactions when compared to individuals with chronically lower arousal levels (Biederman et al. 1995). In support of this theoretical perspective, other investigators have recently found that individuals with autism are more aroused by social stimuli than typically developing individuals and, as a result, may avoid them in order to prevent hyperarousal. This avoidance, in turn, may significantly contribute to social functioning deficits (Corden et al. 2008; Nacewicz et al. 2006; Schultz 2005). While more research is needed to confidently draw the link between arousal, social withdrawal, and social competency, recent studies have shown preliminary but promising leads in the field.

Future Directions

Technological advances in data collection will be imperative to the future study of arousal. In the past, intrusive data collection techniques may have skewed results in that individuals studied may have experienced elevated levels of arousal solely based on the testing situation. If this is the case, these results may only reflect arousal conditions during intrusive testing rather than on arousal states in general. Thus, it is critical to develop the least intrusive measures possible in order to accurately and confidently draw conclusions about true arousal levels that mirror conditions in the natural environment. Similarly, in

order to answer questions about neutral arousal levels and about how individuals with and without autism will react to real-life stressors, future studies should attempt to naturalize the testing setting as much as possible and even aim to collect data in the individual's natural environment.

Other considerations that should be made include providing detailed information about the participants studied. Individuals with autism demonstrate a wide range of functioning levels, and results based on the average of high- and low-functioning individuals are difficult to generalize to any particular subset of the disorder. Further, the use of a developmentally matched control group is crucial in order to control for the effects of general maturation delays (James and Barry 1981; Rogers and Ozonoff 2005). Baseline data should be taken on every individual studied, including control subjects, to determine a range of normal and maladaptive arousal levels, and studies should look at within- and between-group variability as Goodwin et al. (2006) have done. Moreover, future researchers should conduct longitudinal studies in order to better understand the developmental course of arousal. Studying patterns and trends within groups over time may also identify individuals at higher risks for social anxiety and other internalizing or externalizing mental health issues. Finally, the recent push for incorporating biological, neurological, and physiological measures in psychological studies will also undoubtedly bring forth large gains in the field of arousal, social anxiety, and social functioning. Similarly, applied research on this topic has the potential to advance clinical work in the field of behavior and emotion regulation, social anxiety, and social functioning.

- media, the creative process, and the resulting artwork to explore their feelings, reconcile emotional conflicts, foster self-awareness, manage behavior and addictions, develop social skills, improve reality orientation, reduce anxiety, and increase self-esteem. A goal in art therapy is to improve or restore a client's functioning and his or her sense of personal well-being. Art therapy practice requires knowledge of visual art (drawing, painting, sculpture, and other art forms) and the creative process, as well as of human development, psychological, and counseling theories and techniques.
- Today, art therapy is widely practiced in a wide variety of settings including hospitals, psychiatric and rehabilitation facilities, wellness centers, forensic institutions, schools, crisis centers, senior communities, private practice, and other clinical and community settings. During individual and/or group sessions, art therapists elicit their clients' inherent capacity for art making to enhance their physical, mental, and emotional well-being. Research supports the use of art therapy within a professional relationship for the therapeutic benefits gained through artistic self-expression and reflection for individuals who experience illness, trauma, and mental health problems and those seeking personal growth (American Art Therapy Association 2013).

Historical Background of Art Therapy

Throughout time humans have used symbols and images to express themselves. From Egyptian hieroglyphics to mask making to other objects used in rituals, art has been important in creating visual records of self-expression and communication. The development of art therapy has been a process which stems from previous interests in the observation of art and human behavior. In the late nineteenth century, French psychiatrists Tardieu and Simon published studies on the similar characteristics of and symbolism in the artwork of the mentally ill. Shortly after, Ernst Kris made connections to art and psychoanalysis believing in strong links between psyche, artistic works, and

Art Therapy and Autism

Pamela Ullmann

Colors of Play, Oakland, NJ, USA

Definition of Art Therapy

Art therapy is a mental health profession in which clients, facilitated by the art therapist, use art

creative imagination. Like Freud, he believed that artists had an easier time accessing the “id” for material.

The field of art therapy really took form in the 1950s and 1960s. One of the modern pioneers of art therapy was Margaret Naumburg who was primarily an educator, second a psychotherapist, and third the first art therapist. She believed that art was a powerful vehicle in unlocking repressed material. Her perspective, often referred to as “art psychotherapy,” was based on the recognition that an individual’s most fundamental feelings and thoughts coming from the unconscious were expressed more powerfully through images rather than words. Her book, *Dynamically Oriented Art Therapy* was published in 1966 which still serves as an important text to students of the field.

Edith Kramer was another early contributor to the field. Kramer’s approach, “art as therapy,” was developed with her work with children and adolescents who were often unable to describe their feelings with words. Kramer believed that the process of making art allowed the children to access these feelings and identify them through the creative process. Her first book written in 1958, *Art Therapy in a Children’s Community*, described her initial experiences with her clients. After another 13 years of working in a hospital setting and psychiatric ward, she published *Art as Therapy with Children* in 1971. Edith Kramer along with Dr. Laurie Wilson founded the graduate program at New York University in 1976 which was one of the first successful programs and is still active today. It is important to note that Kramer believed that product was as important as process in art therapy. She felt that denying the client the gratification of the end art product was robbing them. Lastly, Kramer believed that the field of art therapy should be in the category of humanities rather than psychology.

Purpose and Underlying Theory

The intention of the art therapist is to offer and share the creative process with their clients in order for them to access their own inner healing.

Art therapy in its totality can be adapted to various theoretical approaches which exist in today’s mental health field. As part of a comprehensive art therapy training, art therapists study psychoanalytic theories, Freudian, Jungian, and others. In addition, art therapy training includes historical and theoretical perspectives of other approaches, such as gestalt, object relations, humanistic, and family therapy.

Within the context of these theories, the art therapist integrates creative modalities and uses artistic media in the sessions with their clients. Sometimes the sessions may combine verbal or “talk” therapy; however, this is not necessary, and the act of art making can be as far as the client wants to go. In any case, while the creative process is taking place, all the art therapists are constantly assessing and tuning into their clients reactions to the materials, the direction that the art is going as well as subtleties in expression and body language.

Benefits of Art Therapy with Individuals with Autism

Autism is a pervasive developmental disorder in which social interactions are the main impairment along with delayed or impaired language development. Individuals with autism are deprived of the resources from which the mind organizes and develops (Emery 2004). Rigid thinking and inability to read other’s emotions tend to be other characteristics that can impede developing healthy relationships.

There are many issues related to sensory processing that affect most if not all diagnosed with autism. Sensory processing disorder (SPD) is a neurological condition that affects the ability to process information from the five senses. Those who suffer with this condition have sensitivities that can cause great distress, discomfort, and confusion leading to behaviors that are seen as “unacceptable” to the outer world. Because of their sensory processing challenges, art making can be a particularly effective therapy for people with autism. Because autistic individuals tend to have

difficulty processing sensory input and are often nonverbal, they respond well to visual, concrete, hands-on therapies. Many people who work with this population know this and whether or not they have art therapy training, including art making in their clients' activities.

There are limitations to our knowledge of why and how therapeutic art making actually works for autistics. These limitations of understanding result from the difficulty of standardized assessments, the near impossibility of quantifying the experience of making art, and the small number of art therapists publishing on the topic. Nonetheless, the abundant amount of research literature explicates that art making is an effective, clinically sound treatment option for autism when supplemented with studies from the fields of art, art education, psychology, and other creative arts therapies (Martin 2009).

Art therapy when used appropriately with individuals with autism can help increase communication, build better social skills, develop a sense of individuality, build more purposeful relationships, and facilitate sensory integration (Betts 2005). Children in particular who are diagnosed on the autism spectrum struggle with these challenges to varying degrees, but communication in general is probably the most difficult of all (Ullmann 2010). The distinct feature of art therapy is the nonthreatening, unpressured environment that it offers to those who are nonverbal. Engaging with art media can be a fulfilling experience that can often help the individual with autism start to feel relaxed with their therapist. In addition, art therapy can incorporate strategies to help individuals build a sense of accomplishment and self-esteem which then may lead to more refined expression and desire to communicate.

Determining the appropriate art interventions for any given autistic individual relies on assessing the developmental level as well as their functionality. Within the broader developmental context, art therapy can be used to engage an autistic individual's relationships to the areas of communication, socialization, and imagination. Art therapy is known to tap into emotional issues; however, the client will probably need to work in the above three domains, before they can be

successful in accessing this higher functioning and deeper area. This can be somewhat counter-intuitive for a majority of art therapists who have extensive experience with other populations which are more capable of insight. Therefore, it is important that the therapist recognize this and do a full assessment of developmental and functioning levels at the beginning of treatment of an autistic child or adult (Ullmann 2010).

One must also keep in mind that children or adults with autism do not ignore others intentionally, but they will tune out in order to help them make sense of their world and regulate their over- or under-stimulated sensory channels. Therapists need to respect this plain fact and resist any impulse to change the process and force the individual to engage before they are ready to. Art therapy can be an excellent intervention when adapted appropriately and when the therapist has a good understanding of the needs of the population. Treatment must be flexible and open, remembering that each individual with Autism is quite different and requires a customized approach.

Articulation

Elizabeth R. Eernisse
Department of Language and Literacy, Cardinal
Stritch University, Milwaukee, WI, USA

Synonyms

Pronunciation; Speech sound production

Definition

Articulation is a general term that refers to the act of producing speech sounds in the vocal tract (i.e., the movement and sequencing of physical structures including the lips, tongue, teeth, jaw, etc.). Speech sounds are often classified based on either the place of articulation (i.e., the physical structures that are involved and where the point of contact occurs between structures) or the manner of articulation (i.e., the amount/type of restriction of airflow involved).

Articulation Disorders

Elizabeth R. Eernisse
Department of Language and Literacy, Cardinal
Stritch University, Milwaukee, WI, USA

Synonyms

Phonological disorders; Speech delay; Speech disorder; Speech sound disorder

Short Description or Definition

Articulation disorders involve difficulty with the correct production of speech sounds. Within the literature, articulation disorders are often differentiated from phonological disorders in that articulation disorders involve motor movements, while phonological disorders refer to the underlying rules/patterns of sound production within a language.

Categorization

Articulation disorders often are classified in terms of severity (e.g., mild, moderate, severe). This rating is typically based on the type/number of errors the individual produces relative to age/developmental norms, as well as a measure of overall intelligibility.

Epidemiology

Shriberg et al. (1999) reported the prevalence of speech delay in a large sample of 6-year-olds to be 3.8% with a male-to-female ratio of 1.5:1. The comorbidity of speech delay and language impairment was reported to be 1.3%. However, estimates of the prevalence of speech sound disorders within the general population have been reported to be as high as 10%.

Natural History, Prognostic Factors, and Outcomes

Within the pediatric population, outcomes for individuals with articulation disorders range considerably depending on the severity of the disorder and the presence of other co-occurring conditions. For children who have been diagnosed strictly with articulation disorders, evidence suggests that with research-supported intervention, many speech sound disorders can be remediated.

Clinical Expression and Pathophysiology

Articulation disorders are typically characterized by the atypical development or production of a speech sound or group of speech sounds that result in a reduction in intelligibility. An articulation disorder is not the result of a cultural or dialectal difference. Disorders may include sound substitutions, distortions, additions, or omissions that impact an individual's ability to be understood in conversation. Speech sounds may be incorrectly produced due to incorrect placement of articulators, imprecise voicing, and/or structural deficits of the larynx, lips, tongue, palate, teeth, and/or jaw.

Evaluation and Differential Diagnosis

Articulation disorders are assessed using standardized tests as well as observational measures. Examples of formal assessments of articulation abilities include the *Arizona Articulation Proficiency Scale, Third Edition* (Fudala 2000); *Clinical Assessment of Articulation and Phonology, Second Edition* (Secord et al. 2002); and the *Goldman-Fristoe Test of Articulation, Third Edition* (Goldman and Fristoe 2000). In addition to standardized measures, samples of speech taken in single word and conversational contexts can be used to determine the type of speech sound errors that are present. Speech sampling procedures may include the assessment of a child's overall phonetic inventory (i.e., the number and variety of sounds he or she is able to produce), an analysis of syllable shapes and phonetic complexity and an analysis of error patterns. Stimulability measures

(i.e., gradually prompting and shaping sounds using cues and feedback from the clinician) often are used to determine if the individual is able to produce the sound given maximal support. In addition to these procedures, best practice suggests that a complete oral-motor examination of the individual be completed to determine if there are any structural or motor function deficits that are impeding correct speech sound production.

Additionally, articulation disorders typically are differentiated from phonological disorders. Careful assessment of a child's speech patterns may reveal not only a difficulty with speech sound production (i.e., a phonetic disorder) but also difficulties with the patterns of use of sounds within the language (see Phonological Disorders).

Treatment

There are a variety of treatment approaches that are used for the management of articulation disorders. Once an individual's specific areas of deficit have been determined, best practice would target the area of need that would most benefit the individual's intelligibility (i.e., how easily his or her speech is understood). Depending on the nature of the problem, treatment may involve individualized speech therapy in which the individual is taught how to produce the sound correctly through demonstration and repeated practice, learning specific techniques to shape how the speech mechanism is used. Additional techniques that are often used include training in recognizing correct and incorrect productions so that the individual can monitor how his or her speech sounds and practicing in contexts that increase in complexity.

ASPEN

Lori S. Shery
 ASPEN (asperger/Autism SPectrum Education Network), Edison, NJ, USA

Membership as of October 2016

Membership is open to families and individuals whose lives are affected by autism spectrum disorders (those formerly known as Asperger

syndrome, PDD-NOS, and high-functioning autism) and nonverbal learning disabilities and the professionals who work with them.

Major Areas or Mission Statement

ASPEN is a national volunteer nonprofit organization with headquarters in New Jersey. It was established in 1997 by a group of parents of children diagnosed with Asperger syndrome to address the increasing need for information, support, and advocacy for individuals on the higher-functioning end of the autism spectrum and their families.

Mission

We will:

- Increase awareness and knowledge among the community and the professionals who diagnose, treat, educate, or provide services to individuals with Asperger syndrome (autism spectrum disorder) and related disorders
- Develop and maintain a strong network of families to support one another through the challenges of daily life
- Encourage the development and support of appropriate programs to foster individual independence and community integration. These programs include:
 - Effective social skills training
 - Social and recreational opportunities
 - Transition services
 - Employment possibilities
 - Transportation alternatives
 - Independent living options
- Advocate for individuals with Asperger syndrome (autism spectrum disorder) and related disorders in schools, the community, and the legislature
- Provide a forum to support and educate affected individuals, their families, and the professionals who work with them

Landmark Contributions

Development and distribution of ASD emergency ID cards, *Intricate Minds* peer awareness video,

college personnel training, law enforcement and emergency responder autism training, and series of employment weekend workshops provided at no charge to individuals on the spectrum and their parents.

Major Activities

Chapters meet monthly, alternating parent-support meetings with speaker presentations that are open to families and professionals. Chapters include those focused on family issues, those focused on adult issues, and those focused on fathers' issues. Additionally, social activity groups are run for pre-teens, teens, and adults. The organization publishes an online newsletter and resource directory, maintains a comprehensive website and lending libraries at each chapter location, holds workshops, and hosts semiannual national conferences featuring some of the most prominent names in the research community in addition to providing staff development and training.

Asperger Syndrome

[Asperger's disorder](#); [Autism spectrum disorder \(ASD\)](#); [PDD](#)

Short Description or Definition

Asperger syndrome (AS) is a developmental disorder characterized by qualitative impairments in social interaction in association with repetitive and ritualistic patterns of behavior. By definition,

there is no clinically significant delay in (1) general cognitive development, as evidenced by IQ in the normal range (i.e., greater than 69), (2) adaptive behaviors, including self-help skills and curiosity about the environment, and (3) expressive language, broadly defined by the use of words by the age of 2 years and phrases by 3 years.

Asperger syndrome, or Asperger's disorder, came to prominence in the 1980s, following the publication of Wing's seminal paper describing 34 young adults with impairments of social interaction and aspects of everyday communication and associated adherence to routine and circumscribed patterns of interest (Wing 1981). The children and young adults described in her paper all exhibited difficulties forming and maintaining relationships with others, with some presenting as aloof and passive, while others actively tried to engage socially, but their communicative exchanges were odd: Unfortunately, therefore, despite their social motivation, their clumsy posture, poor eye contact, and poor vocal intonation denied them the friendships they desired. The majority of the cases Wing described pursued circumscribed, solitary interests with enthusiasm with the result that many acquired a significant knowledgebase on particular subjects.

Wing used the term "Asperger syndrome" to draw attention to the paper first published in 1944 by Hans Asperger, in which four boys with sociocommunicative impairments and repetitive patterns of behavior, including the pursuit of circumscribed interests, were described (Asperger 1944, translated in Frith 1991). She also drew comparisons with the syndrome first described by Kanner in 1943 (Kanner 1943) and, in doing so, brought Asperger and Kanner's syndromes together for the first time and in what has subsequently become known as the "autism spectrum disorders" (ASDs), a tridimensional group of disorders characterized by impairments of social interaction communication and repetitive and ritualistic patterns of behavior.

Since the publication of Wing's paper, there has been considerable interest in Asperger syndrome, as evidenced by the large body of scientific literature devoted to understanding its epidemiology, etiology, and management. There

has also been significant interest in its conceptual relationship to the other "autism spectrum disorders," with much of this research failing to find any evidence of a distinction, thereby supporting the spectral representation (Volkmar and Klin 2005). Indeed, as discussed subsequently, so strong is the evidence that the validity of maintaining Asperger's as a distinct disorder vis-à-vis autistic disorder has been brought into question, and it is quite possible that the term "Asperger's" will not find a place in the subsequent revisions of the World Health Organization's (WHO) International Classification of Diseases eleventh revision (ICD-11) or the American Psychiatric Association's (APA) Diagnostic and Statistical Manual fifth edition (DSM). Nonetheless, as will become apparent, there are a number of reasons for its retention, and even if removed, it is a term that will continue to be used clinically, and therefore it is important for clinicians and health-care workers to have an understanding of its characteristics.

Categorization

In both the American Psychiatric Association's (APA) Diagnostic and Statistical Manual (DSM-IV) and the World Health Organization's (WHO) International Classification of Diseases (ICD-10), Asperger syndrome is categorized along with autistic disorder, Rett's syndrome, childhood disintegrative disorder, and pervasive developmental disorder not otherwise specified (PDDNOS). Much has been written about the relationship between Asperger syndrome and the other PDDs. It is certainly true that the syndromes first described by Kanner and Asperger share many features, and therefore in clinical terms, it is understandable that they have been brought together under the same spectral umbrella. However, what is also apparent is that in bringing these conditions together, many of the features described by Asperger have been subsequently de-emphasized.

For example, Asperger focused on the abnormal patterns of communication that characterized the boys he described. These included abnormalities of social pragmatics, i.e., the everyday

aspects of communication, despite normal formal language skills (such as semantics and syntax). In particular, posture, facial expression, gaze, and other nonverbal communicative gestures were described as notably peculiar. In addition, Asperger commented that language itself, i.e., verbal communication, was of diagnostic importance in view of its peculiarities, which varied from case to case. This included abnormalities with volume of speech (too loud or too quiet), intonation of speech (e.g., talking in a monotone or talking in an overmodulated way resembling exaggerated verse speaking), and in choice of words for communication, which may be formal, pedantic, or otherwise quirky. The importance of the pragmatic aspects of communication is that they do offer some differentiation from the patterns of communication seen in other ASDs, but unfortunately, they are not included in either the DSM-IV or ICD-10.

In addition to this “feature de-emphasis,” the other aspect of our current classification systems that is potentially problematic for the concept of AS is the rule of diagnostic hierarchy. That is, the diagnosis of “autistic disorder” takes precedence over Asperger syndrome, such that if an individual meets the diagnostic criteria for both (and this scenario is not uncommon), then the autistic disorder diagnosis takes priority and the individual is assigned that diagnosis. The result of this is that individuals who may be deemed clinically to have AS are “sucked” into the autistic disorder category.

Although hierarchical diagnosis and symptom de-emphasis may be useful if the spectral conceptualization is correct, as they allow the syndromes of Kanner and Asperger to be more closely aligned, it may be problematic if there is a true difference between the disorders. While it is fair to say that most of the research examining the external validity of differentiating between the two disorders has failed to find any strong evidence for a distinction (discussed in Klin et al. 2005a), much of this research has relied on either the ICD-10 or DSM-IV conceptualizations, and therefore the results come as no great surprise as they are confounded by tautology. In particular, if the two disorders are defined according to the same set of criteria, and if there is a hierarchical

system of diagnosis in place, then the two syndromes may only differ in name.

The only way to overcome this tautological confound will be to re-examine for external validity for groups described according to more robust criteria that offer some possibility of symptom separation (as, it can be argued, would be the case if Kanner’s and Asperger’s original criteria are applied) and if the hierarchical system is removed. One study has explored the external validity of AS in a more objective manner, by comparing features according to three different diagnostic systems, including (1) current DSM-IV criteria, (2) division of the spectrum according to onset of language, and (3) criteria more closely aligned with Asperger’s case studies, which they termed the “new system” (Klin et al. 2005a). This study found that, on balance, their “new system” differentiated greatest between autism, PDDNOS, and Asperger syndrome. Interestingly, while it has also been suggested that IQ profiles differentiate Asperger’s (verbal performance discrepancy favoring the former) from autism (verbal performance discrepancy favoring the latter), no such differences were found for any of the systems used.

Epidemiology

The prevalence of a disorder may vary if researchers use different syndrome defining criteria, and this issue is of crucial significance for AS. For example, before AS was described in the most recent versions of the ICD and DSM, clinicians, eager to diagnose, developed their own criteria. These included those of Ehlers and Gillberg, who subsequently carried out a robust epidemiological study of the prevalence of Asperger syndrome using these criteria (Ehlers and Gillberg 1993). Their criteria were certainly in keeping with characteristics described by Asperger and included the communication items described above, although were fundamentally limited by being very broadly defined. Their study found a point prevalence of 28.5/10,000 (95% CI 0.6–56.5/10,000).

Fombonne (2009), in his overview of ASD epidemiology, took into consideration six more recent

surveys of autism prevalence and found that the rates of AS were consistently lower than autism, with an average ratio of 5:1 for rates of autism versus AS. This translates into a median prevalence estimate of 2.6/10,000 for AS alongside 13/10,000 for autism, and 60/10,000 when more broadly defined cases are included (Fombonne 2009).

In terms of sex ratios, males are more often affected than females, with ratios varying according to diagnostic subtype and level of intellectual ability. In particular, among lower functioning groups, the sex ratio approaches unity, whereas among those who are higher functioning, males are affected more frequently than females. The exact ratio is unclear, with variation between 4:1 and 9:1 being demonstrated between different studies (*ibid.*).

Natural History, Prognostic Factors, Outcomes

Comorbidities

Along with the other ASDs, there are high rates of additional neuropsychiatric disorders among children and adults with AS. Conditions such as epilepsy, tic disorders, and disorders of attention and motor control are known to occur with increased frequency in the ASDs, although no robust data are available for AS. Certainly it is true that for seizure disorders, the highest rates (approaching 20%) are seen among those who are lower functioning, and this is probably true of the attentional and motor disorders too.

In terms of mental health problems, mood and anxiety disorders are particularly common, although due to an absence of epidemiological data, it is not possible to give a true prevalence figure (Woodbury-Smith and Volkmar 2009). In Wing's case series (1981), 8 of the 36 individuals described had "probable depression," and in Tantam's study of 85 individuals with primary social relationship difficulties (1988), many of whom fulfilled the criteria for AS, 11% had clinical depression, this being the most common mental health problem reported (Tantam 1988). It is certainly true that prevalence estimates for comorbid depression vary widely, but taken together,

they suggest that clinical depression is a significant problem in this population. Similarly, anxiety disorders are also commonly reported among individuals with Asperger syndrome. Once again, however, no truly epidemiological study has been carried out, and figures are based on administrative samples. The prevalence of psychotic disorders among AS is less clear, with schizophrenia occurring in three of Tantam's cases (3.5%) and approximately 4% of the "loners" described by Wolff (2000), but none of a clinic-based sample (Ghaziuddin et al. 1998).

Outcome

There is now evidence that as many as 20% will no longer meet the criteria for an ASD as they transition through their adolescent and early adult years, and many others show a significant improvement in their symptoms (Seltzer et al. 2003). Unfortunately, however, studies investigating outcome more generally, including parameters of social inclusion and quality of life such as employment, independent living, and relationships, suggest that the outcome for a significant number is poor (Barnard et al. 2001). This is particularly true of those who are higher functioning, who have the added problem of being excluded from support services because of their normal intellectual function. It is crucial, therefore, that services are developed to meet the needs of this population that will facilitate their social inclusion and thereby improve their quality of life.

It is also apparent that the higher functioning population with ASDs may be at risk of unlawful behavior and contact with the criminal justice system, as discussed elsewhere in this volume. While this may only be true for a small minority, there is some evidence that the core autism phenotype mediates this relationship. In particular, impairment of emotional processing and the pursuit of circumscribed interests may both play a role.

Clinical Expression and Pathophysiology

Clinical Expression

All descriptions of Asperger's have highlighted its core impairment in relating to others. Fairly

consistent has also been the descriptions of communication impairments. Finally, most descriptions highlight the restricted pattern of behaviors, usually taking the form of circumscribed patterns of interest, often solitary, and generally pursued in preference to other activities.

The social impairment is, arguably, the *sine qua non* of Asperger syndrome and all other ASDs. It is characterized by difficulty relating to others. As a result, children with AS are often rejected by, and thereby isolated from, their peers, and as adults may live a fairly solitary existence. In describing Asperger syndrome, Wing highlighted two forms of social impairment, namely, the “aloof” and “active but odd” types, binary categories that have some clinical validation. It is certainly true that most individuals with AS probably fall into the “active but odd type,” with only a minority failing to form social relationships because of aloofness and lack of interest. Instead, many go out of their way to try and form friends, but their approach may be clumsy, with limited use of eye contact, social smiling, or socially recognized greetings. They may dress peculiarly or at least in an unfashionable way. They sometimes fail to appreciate the impact of poor self care on acceptance by others and may stand too close to, or far away from, their interlocutor.

Their communicative exchanges are often formal, particularly noticeable among children who resemble adults in their use of words and formalisms. They may talk in a monotone or over-intonated voice, failing to appreciate the point of “social chit chat,” and may instead chose to present an in-depth monologue about a topic of interest, failing to appreciate whether their listener is interested or bored or, indeed, understands the topic at all. Unfortunately, many people with AS are not interested in the same things as their peers. Among children, for example, an interest in sports, music, and/or fashion is more accepted than cosmology or license plate collecting.

The circumscribed interests are a prominent feature of the disorder, and it is important that they are differentiated from normal patterns of hobbies that many people engage in. Differentiation is unfortunately somewhat arbitrary and

based on interpretation of their intensity and/or focus. To all intents and purpose, an interest is intense to a significant degree if it impinges on other day-to-day activities (such as eating, sleeping, paying bills, and so forth), and is odd in focus if it is not clearly functional (e.g., collecting tin cans). Importantly, it is not unusual for interests to change over time.

Etiology

Much of the literature concerned with the etiology of the ASDs has investigated the spectrum in broad terms, on the assumption that all ASDs share the same causal mechanisms. As indicated previously, there has been research examining the differences between AS and other autistic disorders from a biological (primarily neuropsychological) perspective, but much of this research has failed to differentiate between the disorders. In the discussion that follows, this broader etiological literature will be summarized, but where available, the studies more specifically pertaining to AS will be highlighted.

There is now little doubt that genetic mechanisms play an important role in the etiology of ASDs. Although these same genetic risk factors may be relevant specifically for AS (Rutter 2005), there is a paucity of linkage and association studies specifically examining probands with AS. One study has investigated genetic linkage in AS (Ylisaukko-oja et al. 2004) and observed linkage at 1q21–22, 3p14–24, and 13q31–33 in 17 multiplex families with 119 affected probands, 72 of whom fulfilled the ICD-10 criteria for AS. Interestingly, the loci on chromosomes 1 and 3 overlap with previously identified autism susceptibility loci, and on 1 and 13, with schizophrenia susceptibility loci.

Other research on etiology has focused on looking at neuropsychological mediators of ASDs. This represents a vast literature, although the impairments identified fall into the domains of (1) theory of mind, (2) executive dysfunction, and (3) central coherence (discussed in Klin et al. 2005b). Research using MRI has also identified both structural and functional abnormalities in regions including the fusiform face area, amygdala,

and regions of the dorsolateral and orbitofrontal prefrontal cortices (Schultz et al. 2000).

Unifying all this research into a model of the pathogenesis of autism is difficult. Certainly, the different genes identified all seem to converge on the synapse, and the neuropsychological and neuroimaging research all indicates neural pathways involved in the processing of social and emotional information and mental flexibility. A different perspective aligns the impairments seen in AS with an extreme form of the male brain, with some support for this model existing in the form of the in utero hormonal environment (Baron-Cohen 2005).

Evaluation and Differential Diagnosis

Evaluation

The diagnosis of Asperger syndrome is based upon a detailed clinical assessment, which includes history from an informant who knew the person during their formative years and a direct observation of the person themselves. The autism diagnostic interview (ADI-R) can be used to structure the history, and the autism diagnostic observation schedule (ADOS) can be used to structure the direct observation component. While neither of these contain algorithms specific to the diagnosis of AS, extrapolating from the algorithms that do exist is relatively straightforward. Importantly, these instruments are intended to approximate rather than replace expert clinical opinion. Several other diagnostic instruments have also been developed, including the Australian Scale for Asperger Syndrome (ASAS) and the Gilliam Autism Rating Scale (GARS), and screening instruments specifically for AS are also available (e.g., the autism spectrum quotient (AQ)). Most of these have data on validity and reliability and are commercially available (references available in Woodbury-Smith and Volkmar 2009).

Differential Diagnosis

There are several other disorders that exist at the boundary of the ASDs and which may be

confused with them, particularly among those with ASDs who are higher functioning. This includes schizoid and schizotypal personality disorders, social anxiety disorder, and obsessive-compulsive disorder. The two personality disorders may represent the most diagnostic confusion because of the overlap in clinical symptomatology. Current diagnostic wisdom would argue that the personality disorders develop in late adolescence and early adulthood, which therefore provides a fundamental distinction from ASDs because the latter are of early developmental onset. This is perhaps less helpful than it first appears, however, because in reality, PDs are often symptomatic in earlier adolescence, and the higher functioning ASDs are often characterized by relatively subtle abnormalities during the early years, such that diagnosis is often delayed until the adolescent period and sometimes even adulthood. In all likelihood, the two disorders may represent slightly different manifestations of the same underlying pathological process. Certainly the relationship between Asperger syndrome and the “schizophrenia spectrum” requires further investigation, particularly in light of the genetic evidence discussed above.

Social anxiety disorder is differentiated by the fairly circumscribed nature of the situations that provoke symptoms of anxiety (such as public speaking) and the onset usually in adolescence and beyond. Obsessive-compulsive disorder is differentiated on the basis of the egodystonicity that characterizes the thinking and ritualistic behaviors and the absence of major qualitative social impairments.

Treatment

There is much overlap in the interventions used for AS and other ASDs. In particular, these include those strategies aimed at the core features of the disorder and those aimed at managing comorbidities (Woodbury-Smith and Volkmar 2009). A number of behavioral and educational interventions have been developed aimed at engendering sociocommunicative skills and adaptive functioning and overcoming some of the weaknesses in problem solving and judgment

that occur as a result of executive dysfunction. The evidence base for these interventions is limited and often based on single-case studies or small-case series. Nevertheless, all approaches share a core set of “ingredients,” which include making the treatment individualized, using a “parts to whole” approach, augmented with visual strategies where appropriate, and using explicit, rote verbal learning. Executive dysfunction can be overcome using scheduling, scripts, or lists, and adaptive skills can be taught through practice, rehearsal, and reinforcement. It is also important to recognize that a person with AS can learn though social exposure, either in the form of “buddying” or “circle of friends,” social groups or explicit social skills training. The comorbid mental health problems may also require specific management, through either psychopharmacology or different psychotherapies (as discussed elsewhere in this volume) or a combination of the two.

Synonyms

ASDI; High-functioning autism diagnostic interview

Description

The Asperger Syndrome Diagnostic Interview (ASDI) is a diagnostic instrument developed specifically for the assessment of Asperger syndrome (AS) in children and adults. This brief structured interview consists of 20 items divided into six broader areas of behavior that may be indicative of AS. ASDI is an investigator-based interview in which each item is an open-ended question corresponding to a specific part of autistic symptomatology. It is therefore essential that the examiner acquire a sufficient level of clinical material first so that correct assessment of presented behavior can be made. The evaluation is carried out by scoring each item on the interview as either 0 (does not apply) or 1 (applies to some degree or very much). Total scores are obtained within six different areas. Each area may require a different number of items met to fulfill the diagnostic criteria. ASDI is based on Gillberg and Gillberg's (1989) definition of AS and is congruent with Hans Asperger's original clinical account. Parents, siblings, primary caregivers, or any person well acquainted with the individual's developmental history can also be reporters on the ASDI. Although the ASDI addresses major domains that tend to be problematic in individuals with AS, it can only be considered as one of several steps in the diagnostic process and should not be presented as the only source of inquiry.

- *Area 1 (4 Items): Severe Impairments in Reciprocal Social Interaction (Extreme Egocentricity)*

Items in this area map onto the nature of peer interaction, interest in close relationships, ability to follow social rules, appreciate social communication cues, and the presence of socially and emotionally appropriate behaviors.

(Scoring: Two or more scores of 1 = criterion met)

- *Area 2 (3 Items): All-Absorbing Narrow Interest Pattern(s)*

This area addresses the manifestation of restricted interests that could interfere with development in other domains of functioning.

(Scoring: One or more scores of 1 = criterion met)

- *Area 3 (2 Items): Imposition of Routines, Rituals, and Interests*

Following on the restricted interests, the third area deals with the imposition of routines on one self or others to a degree that impedes functioning.

(Scoring: One or more scores of 1 = criterion met)

- *Area 4 (5 Items): Speech and Language Peculiarities*

Language development is examined in Area 4. Delays in language development are assessed as well as abnormalities in the expressive components of language such as odd articulation, verbosity, and characteristic diction. Appropriate language comprehension, including the understanding of literal meaning and metaphors, is also evaluated.

(Scoring: Three or more scores of 1 = criterion met)

- *Area 5 (5 Items): Nonverbal Communication Problems*

Individuals with AS may display a range of marked nonverbal behaviors such as clumsy gestures, inadequate body language, limited repertoire of facial expressions, or disrupted gaze patterns. Such nonverbal communication impairments are the focus of the Area 5.

(Scoring: One or more scores of 1 = criterion met)

- *Area 6 (1 Item): Motor Clumsiness*

The final domain examines difficulties related to motor coordination in everyday functioning and also inquires about the history of gross and fine motor skill development.

(Scoring: Score of 1 = criterion met)

Historical Background

In 1981, Lorna Wing introduced the diagnosis of AS to English speakers in a case report of 34 children and adults whose clinical observation closely matched Hans Asperger's original case studies but did not overlap with Kanner's criteria for autism at that time. This report initiated further research, resulting in a publication of the first diagnostic criteria for AS (Gillberg and Gillberg 1989), which was revised in 1991. By that time, AS was already a widely recognized clinical diagnosis with several existing screening tools but suffered a paucity of reliable diagnostic instruments that could inform an in-depth assessment. In addition, some authors argued that gold standard measures such as the Autism Diagnostic Interview-Revised (ADIR) and Autism Diagnostic Observation Schedule (ADOS) were not sensitive enough to pick up individuals with these milder yet very distinctive difficulties (Klin et al. 2000).

In 2001, Gillberg and colleagues published the ASDI based on their own diagnostic criteria for Asperger disorder (Gillberg and Gillberg 1989; Gillberg 1991). ASDI was a result of long-term work with a large number of individuals with AS and high-functioning autism with symptomatology difficult to notice through ordinary autism screening tools. Following on Hans Asperger's clinical observations, the diagnostic criteria enlisted in ASDI were different from those in DSM-IV and ICD-10. One of the important differences relates to language development. While DSM-IV requires no clinically significant delay in early language development in individuals with AS, Gillberg, Gillberg, Rastam, and Wentz (2001) argued that such a profile was not seen in clinical practice. Therefore, Gillberg et al. (2001) acknowledged early language impairments as

primary characteristics of AS. In addition, other authors raised concerns about the validity of DSM-IV criteria for AS by documenting that Hans Asperger's original clinical cases would not meet those criteria and would instead fall into the autistic disorder category (Leekam et al. 2000; Miller and Ozonoff 1997). These issues continue to be debated as the ASDI is still used in clinical practice. It was not, however, designed in conjunction with DSM-IV and ICD-10.

Psychometric Data

Participants

Reliability and validity of the ASDI have not been studied extensively. Gillberg et al. (2001) reported preliminary findings on the interrater/intrater reliability in a sample of 24 individuals (aged 6–55) where 17 had a clinical diagnosis and 7 were healthy controls. The diagnosed subjects consisted of 12 cases with AS, 2 cases with atypical autism, 2 cases with obsessive-compulsive disorder, and 1 person with multiple personality disorder. The individuals with AS met some of the criteria for the disorder according to the DSM-IV and full criteria for AS as defined by Szatmari, Bremner and Nagy (1989) and Gillberg and Gillberg (1989).

Reliability

Interrater Reliability

In order to determine the degree of agreement among raters using the ASDI, first-degree relatives of 20 individuals were interviewed by two neuropsychiatrists. The raters were blinded to the diagnostic status of the participants. Both raters were present during the interviews, but only one of them performed the interview while the other one was observing and coding independently. Since the ASDI contains 20 items, each rater had to make 200 ratings. In 383 out of 400 ratings, the two raters reached complete agreement (20 paired ratings), which yielded a kappa statistic of .91 (high level of agreement). The raters had a complete agreement across all items for 10 of 20 individuals, an almost complete agreement (19 items)

in six individuals, and in the remaining four subjects, they agreed on 17 and 18 items. Such results are promising and provide support for a good interrater reliability, although it needs to be acknowledged that the authors used a small sample and only two raters. Further investigation is needed to replicate these findings.

Intrater Reliability

Intrater reliability refers to the degree of consistency of a measure over time. In Gillberg et al. (2001) study, the intrater reliability was determined by a repeated evaluation using ASDI at a 10- to 15-month period after the first assessment. Twenty-four individuals participated in this study, and the examiners were still blinded to their diagnostic status. There was an agreement on 465 out of 480 items corresponding to a kappa of .92. In 16 subjects, the examiner scored accordingly with the previous performance (20 items out of 20), in five subjects, there was a disagreement on one item, for two subjects on two items, and finally, in one case, the differences in rating included seven different items. Based on the results from this sample, the ASDI had very good intrater reliability although the same limitations applied as mentioned in the case of interrater reliability.

Validity

In order to evaluate the construct validity of ASDI, the number of correctly diagnosed individuals has been computed. The ASDI correctly detected all of the subjects with a diagnosis of AS or atypical autism as they fulfilled from five or six (out of six) diagnostic areas. Of the remaining sample, one individual also met criteria for autism despite having a different diagnosis – multiple personality disorder. Based on this sample, ASDI was able to discriminate with high accuracy between individuals with AS and other clinical diagnosis. However, the sample did not include individuals with high-functioning autism, and thus, there is no evidence to conclude that this measure could differentiate between those two categories.

Although the psychometric characteristics of ASDI have shown that this measure has good intrater reliability, interrater reliability, and validity, all of these reported findings are

preliminary and have not been replicated with large samples nor has this diagnostic interview been used in conjunction with other AS measures.

Clinical Uses

The ASDI has been used in AS assessment research, although not extensively. Cederlund, Hagberg, and Gillberg (2010) used the ASDI in their follow-up study in a sample of 100 males with AS who were diagnosed in childhood. The aim of the study was to assess the awareness that individuals with AS had of their emotional and cognitive difficulties and to determine to what extent their view was congruent with their parents' opinion. Seven items of ASDI were administered to both the individuals and their parents. The results showed significant differences between the adults and their parents' scores in three out of these seven items (social ability, social cues, and narrow interests) with parents scoring higher than the individuals with AS. The authors emphasized that these items possibly reflected the core deficits of the social impairments seen in AS and therefore may have been the most difficult ones to be assessed accurately by individuals with AS. Such findings also underscore the extent to which diagnostic interviews rely on the insight and honesty of the interviewed person; yet the population with AS may not be fully aware of their emotional impairments or camouflage them by active learning of socially appropriate scripts. Naturally, the assessment of AS demands a more complex approach. An individual's medical, developmental, and family history needs to be acquired in addition to direct observations of social behavior, psychological evaluation of cognitive functioning, coping mechanisms, and communication skills (Klin et al. 2000). Although ASDI can be used for preliminary diagnostic decisions where AS or high-functioning autism symptoms are suspected, a multidisciplinary assessment guided by an experienced clinical judgment will have the best results for informing the subsequent intervention and deciding whether the diagnostic category matches the clinical presentation and the needs of the individual.

Asperger Syndrome Epidemiology

Marc Woodbury-Smith

Department of Psychiatry and Behavioural Neuroscience, McMaster University, Hamilton, ON, Canada

Institute of Neuroscience, Newcastle University, Newcastle upon Tyne, UK

Definition

The epidemiology of Asperger syndrome refers to what is known about its prevalence and course.

Historical Background

On considering the epidemiology of a disorder, consistency as regards its definition is particularly pertinent, as the prevalence of a disorder may vary if researchers use different syndrome-defining criteria. This is relevant when discussing the epidemiology of Asperger syndrome (AS) for several reasons. First, even before AS was included in the most recent versions of the International Classification of Diseases (ICD, 10th edition, World Health Organization [WHO], 1993) and Diagnostic and Statistical Manual of Mental Disorders (DSM, Volume IV, American Psychiatric Association [APA], 1994), clinicians, eager to diagnose this disorder, developed their own sets of criteria (Klin et al. 2005). Notably, the first two epidemiological surveys of Asperger syndrome, discussed later, both used such “clinician-driven” criteria.

The relatively high-prevalence figure they calculated might reflect the broad nature of the criteria they used, particularly when compared with the generally lower estimates of prevalence for AS subsequently obtained.

Even since its inclusion in the ICD-10 and DSM-IV, with their criteria for AS almost identical, the label Asperger syndrome has often been applied loosely in diagnostic terms, in some cases to mean “mild autism” or “normal IQ autism” or even in everyday parlance synonymously with “loners” or “nerds.” Moreover, even when applying the DSM-IV or ICD-10 criteria, problems with interpretation due to ambiguity of diagnostic items are likely. For example, at what point does an interest become a “circumscribed interest” either in terms of intensity or focus? The subjective threshold of diagnosing clinicians may inflate or reduce prevalence as a result of this ambiguity. And finally, both diagnostic systems include a hierarchy rule, whereby a diagnosis of autism takes precedence over AS, such that if a person meets criteria for both, an autism diagnosis is given. It has been argued that this last point may lead to a situation where an Asperger diagnosis becomes an impossibility, as cases are “sucked into” the autism category. This was formally investigated in a study that revisited the DSM field trial autism-related data. These data included 48 individuals with a clinical diagnosis of AS, of whom 11 (23%) were reassigned a diagnosis of autistic disorder as a result of this hierarchy rule (Woodbury-Smith et al. 2005). As such, the prevalence of the disorder is very likely to vary according to whether a clinician applies this rule.

Current Knowledge

Bearing in mind these caveats, it is perhaps no great surprise that the range of prevalence figures quoted for AS vary widely. For example, the study of Ehlers and Gillberg (1993), using their own diagnostic criteria, found a point prevalence of 36/10,000 among school-aged children (7–16 years) in a school catchment-defined area of central Sweden. This figure rose to 71/10,000 if suspected cases were also included. This same

study also identified a male to female ratio of 4:1 among the definite cases. Ehlers and Gillberg also calculated prevalence using the ICD-10 criteria, which had just been published at the time: a slightly lower figure of 29/10,000 was calculated for definite cases using these criteria. One other study from Sweden (Kadesjo et al. 1999) diagnosed cases according to the ICD-10 criteria and found rates of 48/10,000, with a male to female ratio of 4:1. Due to the fact that samples in both studies originated from small populations (1,401 for Ehlers and Gillberg and 826 for Kadesjo et al.), this prevalence estimate amounted to only a small handful of cases. The Kadesjo et al. study also examined the population prevalence of other autism spectrum disorders, with autism diagnosed according to DSM-III-R and “algorithm ICD-10” criteria. The prevalence of autistic disorder was 60/10,000, suggesting Asperger syndrome is less common than its counterpart.

While the more recent figures also support higher rates of autism than Asperger, the exact prevalence of the latter is somewhat lower than these earlier Swedish studies. The results of more recent prevalence studies (see Fombonne 2009) that include figures for AS are summarized in Table 1. In each of the studies quoted, fairly robust epidemiological methods have been employed and screening and diagnosis are clearly described. On the whole, all these studies seem to agree on a number of points. First, autism is more common than AS. Generally, the ratio was 2:1, although Baird et al. (2000) found a much wider split of 9:1. Secondly, all but one identified prevalence figures between 3 and 10 per 10,000. The one study that found higher figures (Latif and Williams 2007) used Gillberg’s criteria to identify cases which might explain why their figures were closer to those quoted in the earlier studies described above. All the other studies used either ICD-10 and/or DSM-IV.

The lowest prevalence was 3 per 10,000, quoted by Baird et al. (2000). This is the only study that specifically indicated that it ignored the hierarchy rule. It seems reasonable to propose, therefore, that the other four studies quoted in Table 1, which all used the same diagnostic criteria (i.e., DSM-IV or ICD-10), similarly did

Asperger Syndrome Epidemiology, Table 1 Summary of recent epidemiological surveys with Asperger syndrome (AS) data

Country	Size of population	Age range (years)	Autism prevalence (per 10,000)	AS prevalence (per 10,000)	Sex ratio (M:F)	Autism: AS ratio	References
Stafford, UK	15,500	2.5–6.5	16.8 (<i>N</i> = 26)	8.4 (<i>N</i> = 13)	5.5:1	2:1	Chakrabarti and Fombonne (2001)
Stafford, UK	10,903	4.0–6.0	22 (<i>N</i> = 24)	11 (<i>N</i> = 12)	100% M	2:1	Chakrabarti and Fombonne (2005)
South Wales, UK	39,220	Birth–17.0	61.2 (<i>N</i> = 267)	35.4 (<i>N</i> = 154)	6.7–10.5:1	1.7:1	Latif and Williams (2007)
Montreal, Canada	27,749	5–17	21.6 (<i>N</i> = 60)	10.1 (<i>N</i> = 28)	2:1	2:1	Fombonne et al. (2006)
London, UK	16,235	7	27.7 (<i>N</i> = 45)	3.1 (<i>N</i> = 5)	100% M	9:1	Baird et al. (2000)

not apply this rule considering their higher quoted prevalence figures. However, why there should be differences in prevalence when using the same criteria (i.e., ranging from 3/10,000 to 11/10,000) and in urban-based areas in the same country is not clear and may simply be a reflection of methodological differences rather than true prevalence differences.

The studies were fairly consistent in terms of gender split, with the majority of those being identified with AS being males, a figure higher than the 4:1 suggested by Ehlers and Gillberg and Kadesjo and colleagues. This may reflect the fact that diagnosis is more difficult among females or that the phenotype is expressed differently. Of course, the gender difference may be related in some way to the underlying biological mechanisms (such as genes on the X chromosome, or the “extreme male brain” phenotype).

Fombonne (2009), in his overview of ASD epidemiology, took into consideration the six most recent surveys of autism prevalence and found that the rates of AS were consistently lower than autism, with an average ratio of 3.5:1 for rates of autism versus AS. This translates into an estimated prevalence of 6/10,000 for AS alongside 20.6/10,000 for autism and 72.6/10,000 when more broadly defined cases are included (Fombonne 2009).

Future Directions

Therefore, in summary, there are many inconsistencies in the data, but there are a number of factors that might explain these discrepancies. It seems reasonable, however, to conclude that Asperger syndrome is a disorder that predominantly occurs in males and is significantly less common than autistic disorder. Prevalence figures range from 3 to 11 per 10,000 when ICD-10 and DSM-IV criteria are used, ignoring the hierarchy rule, and an estimated median prevalence of 6/10,000 has been suggested. If the hierarchy rule were to be applied, then the figure is likely to be significantly lower. It is also important to recognize that all studies quoted are from Europe or North America, and therefore, the prevalence in other countries is not known. It is even uncertain

as to the prevalence among different ethnic groups in the countries examined.

²Department of Psychiatry and Behavioural Neurosciences, McMaster University, Hamilton, ON, Canada

Definition

Asperger syndrome (AS) is classified as one of several autism spectrum disorders (ASDs) or pervasive developmental disorders (PDDs; American Psychiatric Association 1994). As with other ASDs, the syndrome may be defined as a neurodevelopmental disability that involves significant delays or impairment in social interaction (e.g., age-appropriate friendships, sharing interest or attention with others), communication (conversational skills, nonverbal gestures), and a preference for restricted or atypical interests, stereotypes, or routines. Unlike autistic disorder, individuals with AS do not exhibit clinically significant delays in language development, adaptive functioning, or general intellectual abilities.

There exists considerable variation within clinical work and research as to how AS can be operationally defined using these criteria more precisely. Several researchers have commented that the DSM-IV criteria (APA 1994) are overly restrictive and often result in an underdiagnosis of AS (Cederlund et al. 2008; Howlin 2003; Miller and Ozonoff 1997; Szatmari et al. 1995). Several different definitions have therefore been used in research; however, all share the common features of core ASD deficits in the absence of clinically significant language or general cognitive delay.

Follow-up studies comprise a set of study designs that have the following features in common. The designs are (1) observational, that is, they involve studying individuals that have been naturally selected to a particular group or

exposure as compared to random assignment by researchers to a particular group as in experimental designs; (2) generally prospective, that is, the individuals of interest are followed chronologically and reassessed at one or more later time points; and (3) used to examine predictors and outcomes. Predictors are early factors or characteristics of the individual or his/her environment that are associated with variation in later occurring outcomes. Outcomes may be consequences of a diagnosis or of early predictors of interest.

Follow-up studies are important for several reasons. First, they help to clarify the diagnosis of Asperger syndrome and differentiate it from other ASDs and developmental disabilities. As with many mental health and developmental disorders, the validity of a diagnosis of AS may, at least in part, lie in the ability to distinguish a developmental course with respect to symptoms and functioning over time from other disorders. Second, follow-up studies help individuals, families, and clinicians understand the range of outcomes that may be expected in relation to a diagnosis such as AS, particularly as they relate to important aspects of daily life such as relationships, work, and self-sufficiency.

Prospective cohort studies assemble a group of similar individuals (a “cohort”) at one time point. These individuals are then followed up over one or more time points to determine whether and how variation in certain baseline factors relates to variation in outcomes of interest. If the cohort is followed over three or more time points (including baseline), trajectories or pathways of particular symptoms, abilities, or characteristics may be plotted to describe the rate and shape of change over time. Prospective cohorts are generally considered to produce higher quality evidence among observational studies than cross-sectional or retrospective outcome studies, particularly if they are able to ascertain individuals who are at the same “early” stage of the disorder (e.g., an “inception cohort”). Such designs also minimize error due to recall bias. Drawbacks of these studies include greater expense and length of time to complete data collection.

Retrospective cohort studies also involve assembling a group of similar individuals (e.g.,

individuals with ASD) that nevertheless differ on some traits or factors of interest (e.g., in this case, diagnoses of autism and Asperger syndrome), and are designed to assess whether the type of ASD is associated with differences in outcome. The process of collecting data differs, however. Retrospective studies look back to collect data that has already been recorded in the past to stratify the individuals into subgroups (e.g., records of diagnoses of autism or AS) as well as information on other important predictor (sex) variables or other associated factors. Outcome data may also have been collected in the past or concurrently, as a follow-up to earlier information. Disadvantages of retrospective cohort studies involve sample loss, potentially absent information about important confounders, and reliance on past methods of measurement which may have changed in the interim. Advantages include greater expediency of data collection and lower cost relative to prospective cohort studies.

Finally, *case-control studies* comprise another type of follow-up study, in which individuals with AS are sampled. They are then compared to control groups with respect to rate of earlier predictors or later outcomes of interest. For example, individuals with AS (the “cases”) and higher functioning autism (the “controls”) may be compared with respect to early characteristics and developmental milestones. These studies also have the advantage of saving cost and time to collect data; however, they are at greater risk of bias due to recall effects (e.g., parents of adult children recalling early developmental milestones) and sampling issues (e.g., missing individuals who do not present to a given clinic).

Historical Background

Case reports of children with features resembling Asperger syndrome (AS) were first mentioned in neurological and psychiatric literature in the 1920s (Gillberg 1998). However, Viennese pediatrician Hans Asperger most thoroughly described what he believed to be a new psychiatric disorder, which he termed “autistic psychopathy” (Asperger 1944). His descriptions of children with

disordered “affective contact” were developed around the same time as, but without consultation with, American child psychiatrist Leo Kanner, who also described children with similar traits as “autistic.”

The term “Asperger syndrome” gained significantly greater recognition and interest after it was reintroduced by Lorna Wing in 1981, based on her clinical observations of children and youth who demonstrated obvious autistic features but did not have the cognitive and language delays seen in autism (Wing 1981). An increasing number of publications began appearing to describe individuals with autistic traits who nevertheless demonstrated average or near-average intelligence and language abilities. Asperger syndrome was included in ICD-10 and DSM-IV as one of the pervasive developmental disorders with specific criteria setting it apart from autism and pervasive developmental disorder NOS. Autism and Asperger syndrome were defined as sharing several of the same criteria, with the latter defined as having relatively normal cognitive functioning and language abilities, the absence of language delay, and fewer communication impairments overall. A hierarchical rule was established, such that any individual meeting criteria for both autism and Asperger syndrome would be diagnosed with the former. This rule, as pointed out by many clinical researchers, significantly decreases the number of individuals eligible for a diagnosis of AS (Cederlund et al. 2008; Howlin 2003; Szatmari 2000). Accordingly, definitions of AS have varied across research studies, in efforts to capture samples of individuals who reflect a “true” picture of the disorder.

In spite of this growing literature, there have been relatively few prospective follow-up studies of Asperger syndrome, as distinct from other pervasive developmental disorders and, in particular, high-functioning autism. Gillberg and colleagues followed up young men who had been diagnosed with Asperger syndrome 5 or more years earlier (Cederlund et al. 2008), whereas Szatmari and colleagues followed a cohort of children aged 4–6 recently diagnosed with Asperger syndrome and high-functioning autism every 2–4 years into adolescence (Szatmari et al. 2000). Other studies

used individuals with AS and high-functioning autism who have presented as adolescents or adults to clinical services and then examined current and retrospective features associated with the diagnosis (Gilchrist et al. 2001; Howlin 2003). The differing study designs and definitions of AS have led to some variation in results, particularly regarding the extent to which AS is distinct from high-functioning autism. However, all share the common goal of understanding how individuals with AS fare as they age into adulthood with respect to symptoms, adaptive functioning, and quality of life.

Current Knowledge

Follow-up studies of individuals with Asperger syndrome (AS) have been few in number and have differed widely with respect to their overall design, the definition of Asperger syndrome used, the sampling methods for finding cases with AS, the type of comparison group employed, and how predictors and outcomes are measured (Cederlund et al. 2008; Gilchrist et al. 2001; Howlin 2003; Szatmari et al. 2003, 2009). Nevertheless, they share a common goal of understanding how individuals with AS fare in later childhood, adolescence, and adulthood with respect to important outcomes of interest – their core developmental abilities and their overall level of adaptive functioning as individuals in society. Understanding the course of development and outcomes in Asperger syndrome is related to the predictive validity of the diagnosis: whether the disorder helps forecast a developmental pathway for AS that is distinct from that of Autistic Disorder in a measurable and meaningful way. More importantly, it helps individuals and their families understand the implications of such a diagnosis and plan for their future, while aiding clinicians in service development by anticipating their future needs.

Childhood

Studying the short-term outcomes of children with Asperger syndrome sheds light on baseline variation between children with autism spectrum disorders and the importance of early developmental

“head starts.” For example, Szatmari et al. (2000, 2003) followed up 68 children aged 4–6 years old who were diagnosed with either autistic disorder or Asperger syndrome and had IQs of at least 68 standard score points (Szatmari et al. 2000, 2003). Children diagnosed with Asperger syndrome had significantly better socialization scores on the Vineland Adaptive Behavior Scales at baseline and 2 years later compared to children with autistic disorder, controlling for initial language ability and nonverbal IQ. Children with autistic disorder who gained functional language over the course of the follow-up period achieved socialization scores similar to the Asperger syndrome group at baseline. These early studies indicated that children with Asperger syndrome seem to embark on parallel, but higher functioning, trajectories compared to peers with autistic disorder and that the achievement of verbal fluency may act as an important early differentiating step between developmental pathways (Szatmari et al. 2009).

Adolescence and Early Adulthood

The evaluation of how well individuals with Asperger syndrome fare in adolescence and early adulthood understandably depends upon the group to whom individuals with AS are compared. Researchers using data from two separate prospective follow-up cohort studies (Bennett et al. 2008; Cederlund et al. 2008; Szatmari et al. 2009) found that young adults with AS have better outcomes with respect to ASD symptom burden and adaptive functioning compared to individuals with autistic disorder (including high-functioning autistic disorder with IQ > 70). In a prospective study of young adults with AS, outcomes were classified as poor (“obvious severe handicap, no independent social improvement”), restricted, fair, and good outcomes (engaged in IQ-appropriate work or education and living independently if over 23 years of age or having steady friendships/relationships if younger than 23) (Cederlund et al. 2008). Only 26% of individuals with AS were classified as having “poor” or “restricted” outcome, compared to 64% of those with AD. Retrospective case–control studies have found few if any differences (Gilchrist et al. 2001;

Howlin 2003). A common consensus among studies, however, is that young adults with AS – despite normal-range IQ and absence of early language delays – have striking difficulties across a wide range of domains compared to typically developing individuals. For example, despite a mean full-scale IQ for the AS group of 103.0 in Cederlund et al.'s (2008) study, 47% were classified as having “fair” and only 27% were deemed to have “good” outcomes.

Core ASD Symptoms

A majority of individuals with AS continue to struggle with significant social communication deficits in early adulthood accompanied by significant associated impairment, with the exception of a small number who appear to improve significantly into a relatively unimpaired status (Cederlund et al. 2008). One study found that the mean Global Assessment of Functioning Score (GAF) – a clinical measure of impairment due to symptom burden – was 58.9, indicating moderate symptom burden or impairment. However, 17% of individuals with AS in this study had GAF scores greater than 70, indicating normal or near-normal functioning; 11% of all those diagnosed with AS and later followed up no longer met criteria for AS. As a group, individuals with AS demonstrated less impairment than individuals diagnosed with autism as children (mean GAF = 22.4). However, in a study comparing individuals with AS with high-functioning individuals with autistic disorder, there were no significant differences in ASD symptoms as measured by the autism diagnostic interview-revised (ADI-R; Lord et al. 1994).

Nevertheless, autistic symptoms seem to decrease over time in individuals with AS, as an overall group (Szatmari et al. 2009). Researchers examining the rate of change in core autistic symptoms found a relatively linear rate of decrease from preschool to adolescent years, with a slightly faster rate of change between ages 5–10 years (Szatmari et al. 2009). This rate of change was similar to that for a group of autistic individuals with IQ > 70; however, those with AS maintained a comparatively lower burden of symptoms overall from childhood into late adolescence.

Cognitive Profile

Cognitive abilities as measured by full-scale performance and verbal IQ have generally been found to be stable from childhood to adolescence/early adulthood in AS (Cederlund et al. 2008). There is some evidence that the relative superiority of verbal IQ over performance IQ often described in individuals with AS compared to individuals with autism is less common by adolescence/young adulthood (Cederlund, et al.).

Comorbid Psychiatric Symptoms

Outcome studies indicate that psychiatric comorbidity is a common problem for individuals with AS, with rates similar to those of individuals with high-functioning autistic disorder and PDD-NOS but higher than those seen in the general population (Hofvander et al. 2009; Howlin 2003). Mood and anxiety disorders appear more commonly in adolescence and young adulthood than childhood, occurring in 21–52% of individuals with AS according to two case-control studies (Hofvander et al. 2009; Howlin 2003). Attention-deficit/hyperactivity disorder (36%), tic disorder (21%), and obsessive-compulsive disorder (21%) have also been found to be more common than in controls (Hofvander et al. 2009). Rates of psychotic disorders measured in clinical and population samples of individuals with AS range from 4% to 15% (Cederlund et al. 2008; Hofvander et al. 2009).

Adaptive Functioning

Perhaps the most striking burden of Asperger syndrome in adolescence and adulthood falls under the domain of adaptive functioning – the ability to support oneself in day-to-day self-care, independent living, and financial self-sufficiency, to engage in relationships and to pursue vocational interests. Adaptive functioning is an important measure of impairment related to AS, as well as an indirect measure of burden of care on parents, schools, and community systems of care. Furthermore, adaptive functioning has been found to be associated with self-reported quality of life among individuals with high-functioning ASD (Kamp-Becker et al. 2010). Prospective research has found that individuals with AS

demonstrate significant improvement in adaptive functioning throughout childhood to adulthood, with some slowing of progress during adolescence. It must be remembered, however, that individuals with AS remain significantly impaired compared to the general population (Szatmari et al. 2009).

Educational achievement appears to be a relative strength among individuals with AS. A greater number of individuals with AS achieve advanced levels of schooling, compared to those with autism. In one study, twice as many individuals with AS (52%) completed advanced level high school courses as did those with high-functioning autism (24%) (Howlin 2003). Another study found that 11.4% of individuals with AS enrolled themselves in university, and 5.6% had obtained university degrees, while 33% completed high school studies. Among high-school completers, over half (64%) completed their studies in mainstream classrooms (Cederlund et al. 2008).

Such academic abilities do not seem to translate into longer term vocational success or self-sufficiency, however. Only 5–10% of individuals with AS hold permanent, well-paying jobs in adulthood, whereas a greater number work in short-term, low-pay, or voluntary posts or structured work activities in a support center (Cederlund et al. 2008; Howlin 2003). Furthermore, despite normal IQ abilities, only 35–64% of young adults with AS live independently, the majority of these requiring ongoing parent support (Cederlund et al. 2008; Howlin 2003).

Consistent with reports of persistent social disabilities related to their diagnosis, individuals with AS report ongoing difficulties in maintaining social and romantic relationships. Approximately 4–15% of individuals report long-term relationships such as longstanding close friendships, romantic partnerships, or marriage (Cederlund et al. 2008; Howlin 2003), although a larger number of individuals (40.5%) in one study reported having a range of less intimate friends and acquaintances (Howlin 2003). Nevertheless, individuals with AS remain persistently less impaired than are individuals with autism (including high-functioning autism) from childhood into adulthood (Szatmari et al. 2009).

Predictors of Adolescent Outcome

IQ and language abilities have been found to be important predictors of improved functioning in adolescents and adults with AS and HFA (Bennett et al. 2008; Cederlund et al. 2008; Szatmari et al. 2009). This finding is in keeping with research combining ASDs of all cognitive abilities (Baghdadli et al. 2007). Higher full-scale and verbal IQ scores are associated with improved overall outcome in adolescents and young adults with AS (Cederlund et al. 2008). Because AS is defined largely by the absence of clinically significant language delay in most research studies, this feature has been proposed to account for improved outcomes compared to individuals with autism and IQ > 70 found in prospective studies (Cederlund et al. 2008; Szatmari et al. 2003), although not in retrospective investigations (Gilchrist et al. 2001; Howlin 2003). Structural language impairment at age 6 years, defined as significant deficits in non-pragmatic aspects of language (e.g., grammar, syntax), has been found to predict greater variability in functional outcomes across social, communication, and daily living skill domains in adolescents in high-functioning ASD than the presence of language delay (Bennett et al. 2008; Szatmari et al. 2009). This suggests that structured assessments of language as well as cognitive ability in preschool/early school-aged years are important early steps in understanding the prognosis of children with high-functioning ASDs. There is evidence of persistent language impairment in individuals with AS compared to typically developing norms (Howlin 2003); however, its role in predicting outcomes more specifically within this group has yet to be studied systematically.

Summary and Conclusions

In evaluating how individuals with AS fare in adolescence and adulthood, it is important to consider the standards against which they are being compared. According to prospective follow-up studies, the outcomes of individuals with AS are significantly better compared to those with autistic disorder, including high-functioning autism. This is likely a function of better cognitive and

language ability, which puts them at an early and persistent advantage compared to lower functioning peers with autism. However, given these cognitive capacities, young adults with AS continue to have difficulty living and working independently and remain significantly burdened by social impairment. Furthermore, rates of early improvement in functioning begin to plateau in late adolescence, which may reflect slowed learning or simply an inability for this learning to keep pace with the increasing functional demands of transition to adulthood. These findings highlight the obvious need for continued vocational, social, and daily living supports for teens and adults with Asperger syndrome.

Future Directions

Despite a relatively small number of follow-up studies of young people with Asperger syndrome published to date, the data clearly demonstrate that as a group, their functioning and well-being in adolescence and adulthood are poor relative to typically developing individuals. This consensus underlines the importance of having a better understanding of how early determinants and developmental pathways lead to variation in outcomes. While prospective studies suggest that improved cognitive and early language abilities account for superior outcomes in Asperger syndrome compared to autistic disorder, more work is needed to understand early predictors within groups of individuals diagnosed with AS taking into account the considerable heterogeneity in outcome in this population. Future longitudinal studies should focus on unpacking *how* early predictors lead to later outcomes, for example, through *mediators* (individual or contextual factors that account for the association between predictors and outcomes) or *moderators* (groups or circumstances under which an effect occurs or not). For example, poorer mental health may mediate, or explain, an association between earlier individual traits or cognitive abilities and later adaptive functioning in certain individuals.

Future study designs that combine intervention and longitudinal follow-up will be particularly

important in both elucidating developmental pathways in Asperger syndrome and addressing the suboptimal outcomes that all too often occur. Hybrid studies may include intervention trials (ideally randomized and controlled) and long-term measurement of outcomes. Early social communication interventions, prevention, or treatment trials for depression and anxiety and more intensive social, communication, and vocational supports for adolescents may each demonstrate effects on more global or specific aspects of functioning and quality of life in adulthood. Finally, follow-up and intervention studies should also follow individuals with Asperger syndrome farther into adulthood to continue to track their pathways in learning and functioning and to determine how best to encourage their strengths and support their needs.

Asperger Syndrome Training & Employment Partnership (ASTEP)

Michael Carley
Green Bay, WI, USA

The Asperger Syndrome Training & Employment Partnership (ASTEP) is a nonprofit 501(c)3 organization that promotes the inclusion of individuals with Asperger syndrome and high-functioning autism (AS/HFA) in competitive employment through:

1. Awareness and training campaigns aimed at Fortune 1000 companies
2. Establishing relationships between high-quality support programs for adults with Asperger throughout the US and national employers
3. Developing corporate partners to implement integrated employment programs for adults with Asperger syndrome

Founded in 2010 by Marcia Scheiner, ASTEP was created to fill a hole in the autism/Asperger world. Prior to ASTEP, numerous opportunities existed for job placement, but no organizations were helping employers create more inclusive workplace environments for existing employees with AS/HFA or bringing together employers and vocational support professionals to successfully recruit and integrate individuals with AS/HFA. ASTEP does this by educating employers and building relationships.

ASTEP educates employers about the special skills and talents of individuals with AS/HFA, the business benefits of employing people with Asperger syndrome, and the accommodations they may need in the workplace. It encourages employers to incorporate the hiring and retention of individuals with AS/HFA into their diversity and inclusion programs and gives them the tools and training they need to feel confident. ASTEP offers video-based corporate training opportunities, as well as on-site training presentations.

ASTEP also builds relationships with vocational support organizations to facilitate employer access to candidates with AS/HFA. Vocational support organizations can be privately funded organizations, state or federally funded organizations, or postsecondary educational programs that provide specialized support for students and young adults with AS/HFA.

While ASTEP does not provide support services to individuals looking for work opportunities, it offers web resources and programs to assist such individuals on their job hunt on ASTEP's Assistance for Individuals page.

For more information on ASTEP and its programs, you can email them at info@asperger-employment.org, or visit their webpage at www.asperger-employment.org.

Asperger, Hans

Adam Feinstein

Autism Cymru and Looking Up, London, UK

Major Appointments (Institution, Location, Dates)

- Hans Asperger was appointed director of the play-pedagogic station at Vienna University children's clinic in 1935.
- Appointed a lecturer at the University of Vienna, 1944.
- Appointed director of the children's clinic, 1946.
- Named professor at the University of Innsbruck children's clinic, 1957.
- Named professor at the University of Vienna children's clinic, 1962.

Landmark Clinical, Scientific, and Professional Contributions

Dr. Asperger was working in the field of what he called "autistic psychopathy" in Vienna from the early 1930s – several years before Leo Kanner began working on infantile autism at Johns

Hopkins University in Baltimore. His first published paper in this area was not the celebrated 1944 paper but "Das psychisch abnorme Kind," which appeared in the *Wiener Klinischen Wochenschrift* in 1938 (Asperger 1938). This was the transcript of a talk Asperger had given at Vienna University earlier that year. It is a remarkable document: Asperger, concerned to protect the children in his charge from the eugenics law which he feared would be introduced by the Nazis in the newly annexed Austria, carefully used terminology reminiscent of Nazi thinking while at the same time pointing out the valuable contributions the children could make to society. The Gestapo came to arrest him twice, but he received the support of his boss – Franz Hamburger, dean of the university – who ironically, unlike Asperger, was sympathetic to the Nazis. Asperger's 1944 paper, 'Die autistischen Psychopathen' im Kindesalter – which appeared in *Archiv für Psychiatrie und Nervenkrankheiten* – provided detailed descriptions of four children with autistic psychopathy, or what Lorna Wing, in 1981, called "Asperger's syndrome" (Asperger 1944; Wing 1981). Unlike in classic (or "Kanner's") autism – where there is language delay and IQ can be anywhere on the scale – in Asperger's syndrome, there is no language delay and IQ is at least average. Asperger believed that his syndrome was never recognised in infancy and not usually before the third year of life or later. Kanner emphasised onset of his condition from birth or before 30 months. Unlike Kanner, Asperger thought of his condition as a personality disorder with organic causes. While Kanner reported that three of his 11 patients did not speak at all, and the remainder rarely used language to communicate, Asperger noted that his case study patients spoke "like little adults". There were also discrepancies regarding gross co-ordination and fine motor skills. Kanner reported that, although the former was poor the latter was very good. Asperger observed that both were affected. Kanner believed that learning by rote would be the best method of advancing an autistic person, while Asperger suggested that his patients were "abstract thinkers" and therefore performed best spontaneously. Asperger said his patients were highly intelligent and capable of original thought. He referred to them as "little professors".

Short Biography

Hans Asperger was born on a farm outside Vienna on February 18, 1906. He was appointed director of the play-pedagogic station at Vienna University children's clinic. He married in 1935 and had five children, including two daughters who themselves became doctors. In the later part of the Second World War, Asperger served as a doctor in Croatia. His daughter, Dr. Maria Asperger Felder, told Adam Feinstein: "He was against war. He was a nature- and people-loving person, not a soldier." In 1944, he became a lecturer at the University of Vienna and was appointed director of the children's clinic in 1946. In 1957, Asperger became professor at the University of Innsbruck children's clinic and, from 1962, held the same position in Vienna. Despite the fact that he traveled around the world, his writings were not mentioned at a major psychiatry conference in Zurich in April 1957. The veteran French autism authority, Professor Gilbert Lelord, who attended this congress, told Adam Feinstein that this may well have been a consequence of the Second World War: "Even though Asperger was undoubtedly a victim of the war, German-language papers were not popular at the time." Indeed, Asperger's writings did not come to the attention of the English-speaking world until Lorna Wing's 1981 paper and Uta Frith's 1991 translation into English of Asperger's 1944 paper. Leo Kanner never mentioned Asperger in any of his own papers, whereas Asperger often cited Kanner, always insisting that his syndrome was distinct from Kanner's. Asperger's syndrome was listed officially for the first time in ICD-10 in 1992 and in DSM-IV in 1994.

Aspire: The Asperger Syndrome Association of Ireland

Desmond McKernan
Asperger Syndrome Association of Ireland
(Aspire), Dublin, Ireland

Introduction

The Asperger Syndrome Association of Ireland Ltd. (Aspire) was established in 1995 as a registered charity (CHY 11438) and a company (incorporation No. 231996). The original founders were a small group of parents who were concerned at the lack of awareness and information concerning Asperger syndrome or high-functioning autism among parents and professionals and the absence of services specifically designed for those with the condition. The association was set up to provide support to individuals who have Asperger syndrome/high-functioning autism and their families and other caregivers and to encourage and undertake research into the condition.

Address: The Asperger Syndrome Association of Ireland Ltd., Carmichael Centre for Voluntary Groups, Coleraine House, Coleraine Street, Dublin 7, Republic of Ireland.

Membership: On the 31st of December 2013, the number of registered members of the association was 220.

Website: www.aspireireland.ie

Mission Statement: The mission of the association is to assist people with Asperger syndrome/

high-functioning autism to lead more fulfilled lives and to support their caregivers.

Landmark Contributions

The major landmark contributions of the Aspire have been the raising of awareness of Asperger syndrome/high-functioning autism and the development of services to assist people with the condition and their caregivers. When the association was set up, there was very little information available and no services specifically developed for people with this form of autism in Ireland. Since 1995, the Aspire Helpline, the holding of regular conferences/seminars and courses each year together with the development of the Aspire website, has improved the awareness of Asperger syndrome in Ireland. The association has also encouraged and assisted in the production of a range of programs on radio, TV, and other media to highlight the disorder. Professor C. Gillberg addressed a conference in Dublin, Ireland, organized on the tenth anniversary of the founding of the Aspire. In 2006, the Honorary Secretary of the Association received an award from Dublin City Council for his voluntary work, over the previous 11 years, in raising awareness of Asperger syndrome/high-functioning autism in Ireland. Every year visits to schools are a priority in the Aspire awareness-raising campaign.

A major conference was held in October 2010 to address the co-occurrence of conditions such as Asperger syndrome with dyspraxia, hyperactive disorder, and dyslexia. This conference was the first of its kind to be held in Ireland.

In 2009, Aspire in conjunction with Trinity College Dublin produced a DVD entitled "Asperger Syndrome: A Practical Guide for Parents, Teachers, Young People and Other Professionals," and this was circulated to all public schools in the Republic of Ireland. A landmark conference was also held at Trinity College in November 2013 entitled "Challenging DSM 5," and international speakers Professor F. Volkmar and Professor P. Howlin spoke on the changes being introduced in the diagnosis of autism by the American Psychiatric Association under DSM 5.

The setting up of Educational Drama Classes in collaboration with the School of Education at

Trinity College Dublin in September 2004 was a major contribution in the development of services for children, adolescents, and adults affected by Asperger syndrome/high-functioning autism. These classes have made a significant contribution to improving the social and life skills of participants and over the past decade have shed new light on the methods used in the teaching of social skills. The identification of a large number of subtypes within the diagnosis of Asperger syndrome/high-functioning autism by Dr. Carmel O'Sullivan (Director of the Drama Classes) has been a significant milestone in the understanding of the disorder.

Landmark Activities: The most important activities of the association are:

The provision of a Helpline available to Aspire members and the general public from Monday to Friday. These telephone contacts with a large number of people keep Aspire up to date with the issues families are experiencing and identify the problems currently being encountered – mainly by parents. The supports provided by Aspire are tailored to take into account the issues raised on the Helpline.

Raising awareness and understanding of Asperger syndrome using all the media available assists people with a diagnosis of Asperger syndrome to develop their potential in a more understanding and supportive environment.

Provision of Educational Drama Classes to teach social skills to those with a diagnosis of Asperger syndrome/high-functioning autism.

A supported employment and career development service for adults with a diagnosis of Asperger syndrome/high-functioning autism.

Holding regular conferences, seminars, courses, and workshops for all those interested in the condition.

Assisting support groups set up to provide assistance to those affected by Asperger syndrome/high-functioning autism and their caregivers.

Residential unit for adults with Asperger syndrome/high-functioning autism.

Major Areas of Activity

Aspire Helpline service provides contact with over 1,200 callers each year who are seeking

information, support, and advice. Topics of enquiry range from diagnosis, education, assessment, social skills, adult issues, local services, training, and general information. The majority of callers are parents of children with Asperger syndrome or those seeking a diagnosis. The Helpline also receives a large number of calls from adults with the disorder and professionals such as teachers and journalists.

Educational Drama Classes (in Conjunction with Trinity College Dublin) Provide Social Skill Training to About 90 Children, Adolescents, and Adults
Aspire maintains a website with up-to-date information about Asperger syndrome, the latest news and events, including fund-raising, together with general information.

It is divided into information for parents and professionals and information for people with Asperger syndrome. Aspire also keeps up to date using social media through Facebook and Twitter, to ensure that the information we provide is easily accessible to as wide a population as possible.

Aspire supports over 30 groups which were set up to support people with Asperger syndrome and their families. Aspire assists volunteer parents and people with Asperger syndrome to set up the groups and visit and provide informational talks to these groups where required. We also direct any families who contact us to their local group(s). This type of peer support has been found over the years to be extremely important and a hugely valuable resource provided at very low cost.

Aspire visits a large number of schools and third-level institutions each year to promote an understanding of Asperger syndrome and to advise on the supports which need to be provided to students with the disorder.

These visits are made to enhance the educational experience of students with Asperger syndrome and ensure that they have the opportunity to get the best from their educational experience which will aid them in later life in gaining and maintaining employment.

Adults who have Asperger syndrome struggle to find suitable employment as a result of

challenges with communication, social interaction, and anxiety. As adult services are limited in Ireland, Aspire has developed a supported employment and career development program for adults with Asperger syndrome. The needs of participants are identified, and they are supported in areas such as CV preparation, interview skills, interaction with colleagues, and applications. Aspire also liaises with employers to ensure that they have an understanding of Asperger syndrome and provide them with relevant information and support.

Assessing Quality of Life in Autism

Leann Smith DaWalt, Marsha R. Mailick, Jan S. Greenberg and Jinkuk Hong
Waisman Center, University of Wisconsin-Madison, Madison, WI, USA

Definition

Given the complex and diverse lives of individuals with autism spectrum disorder (ASD), it is valuable to apply a comprehensive conceptualization of quality of life (QoL) when assessing life course and treatment outcomes for individuals with ASD. In the general population, QoL is considered a multidimensional construct. For example, the World Health Organization defines subjective QoL as an “individuals’ perception of their position in life in the context of the culture and value systems in which they live and in relation to their goals, expectations, standards and concerns” (WHOQOL Group 1995, p. 1405). Accordingly, standardized measures of QoL in the general population typically include items in the physical, psychological, and social domains (Danckaerts et al. 2010). For individuals with developmental disabilities, including ASD, researchers have similarly applied a multidimensional framework to the study of QoL. One of the most commonly utilized definitions comes from the work of Schalock and colleagues who drew upon concepts from the literature in the

general population and applied them to individuals with developmental disabilities, resulting in eight key areas of QoL: interpersonal relations, social inclusion, personal development, physical well-being, self-determination, material well-being, emotional well-being, and human and legal rights. For individuals with ASD, other related markers of a high quality of life also have been suggested such as social participation with family and community, having choices, feelings of happiness, and satisfaction and meaning in work (Ruble and Dalrymple 1996). Drawing from these definitions, most contemporary measures of QoL for individuals with ASD include multidimensional components reflecting subjective and objective characterizations of QoL across a range of contexts.

Historical Background and Measurement

In the general population, QoL is typically measured by self-reports capturing personal appraisal of various life domains. However, for individuals with ASD, this measurement strategy can pose unique challenges due to the impairments in communication and/or cognitive functioning that many individuals across the range of the autism spectrum face. To address such potential barriers to the study of QoL, Verdugo et al. (2005) proposed several relevant guidelines for measurement of QoL among individuals with developmental disabilities, namely, that in addition to the individual with the disability acting as the respondent, family members likewise can report on the QoL of the individual. Further, it may be valuable to gather information on QoL using both quantitative and qualitative methodologies and to probe questions related not only to common/universal experiences across physical, social, and cultural contexts, but also to experiences that are more unique to individuals with disabilities (Verdugo et al. 2005). For example, while most population-based measures of quality of life will include multiple general indicators of health, for individuals with disabilities additional questions such as items regarding choice or

empowerment in health care decisions may be needed for a more holistic understanding of quality of life for that dimension. These multi-informant, multimethod approaches allow for a fuller characterization of quality of life for individuals than self-report alone and have been successfully employed in studies of individuals with developmental disabilities including ASD.

Below we discuss specific measures of QoL that have been utilized in the past two decades in samples of individuals with ASD. We summarize measures that include a self-report option and also provide an overview of measures that are exclusively parent or caregiver report. We note that some of these measures were developed for general populations, thus reflecting universal experiences (and subsequently were administered to individuals with ASD or their family members, potentially with modifications), whereas other instruments were intentionally designed to assess QoL dimensions specifically for individuals with disabilities from the onset. Further, some measures focus more on the perspectives of the individual with ASD (either through self-report or proxy report), whereas others gather information about the environment (e.g., presence/absence of activities). Notably, given the diversity of the autism phenotype, particularly in the areas of information processing and reading comprehension, self-report measures designed for the general population may be appropriate for some individuals with ASD without modifications, whereas for other individuals, significant modifications may be needed. For others, some self-report measures simply may not be accessible. In contrast, certain items from measures developed specifically for individuals with intellectual and developmental disabilities and/or ASD may not be relevant for all individuals with ASD depending on age and level of functioning. As such, when selecting measures of QoL, special consideration should be given regarding the intended purpose of the instrument and the populations for whom it was designed and with whom it has been validated.

The *Pediatric Quality of Life Inventory* (PedsQL 4.0; Varni et al. 2001) is a QoL measure designed for pediatric groups in the general population that has both child self-report and parent

proxy report options. The inventory includes subscales (physical functioning, emotional functioning, social functioning, and school functioning) and has 23 items which assess how much of a problem the child has had in the past month on a 5-point scale (0 = never a problem to 4 = almost always a problem). There are versions for different age groups (e.g., young children vs. youth/young adults), with response options reflecting the developmental level of the respondent. For example, the version for young children (ages 5–7) includes simplified language and happy/sad faces. The PedsQL self-report version has been successfully employed in samples of adolescents with ASD with IQs of 70 or greater (Shipman et al. 2011; Sheldrick et al. 2011), with a strong correlation between the adolescent and parent report versions ($r = .40^*$; Shipman et al. 2011). The parent report of the PedsQL also has been used with children with ASD as part of the Autism Treatment Network (Kuhlthau et al. 2010) and in sample of children with Asperger's (Limbers et al. 2009).

The *World Health Organization Quality of Life Instrument, Abbreviated Version* (WHOQOL-BREF; WHOQOL Group, 1998) is a widely used 24-item self-report questionnaire of subjective QoL designed for adults in the general population across multiple cultural groups. However, this measure can also be administered through proxy or other report. The WHOQOL-BREF assesses QoL in four domains: (1) physical health, (2) psychological health, (3) social relationships, and (4) environment. The measure has a 5th-grade reading level and has been successfully implemented in samples of adolescent and young adult males with Asperger syndrome/HFA (Kamp-Becker et al. 2010; Jenees-Coussens et al. 2006). There is also a disability-specific module available (Power et al. 2010). In a recent study of adults with ASD aged 25–50 across a range of intellectual functioning (30% had cooccurring intellectual disability), adults with ASD were shown to rate their own QoL reliably using the WHOQOL-BREF (Hong et al. 2016). Notably, for this study, screening was conducted prior to administration of the measure (e.g., record review to document general comprehension skills and practice items with respondents to gauge

understanding). Modifications also were made to the instrument to increase accessibility such as including additional words/phrases to add clarity when the original wording was difficult to understand (e.g., “Are you able to accept your bodily appearance” was supplemented with “Do you like how you look?” if the participant asked for help in understanding the question) and providing visual supports for response categories (e.g., a response card showing facial expressions, such as a broad smile to a deep frown, for each response option; Hong et al. 2016).

Following the comprehensive conceptualization of QoL put forth by Schalock and colleagues, two self-report QoL measures have been developed specifically for individuals with intellectual and developmental disabilities; these measures include items that cover a range of areas relevant to disability and are accessible for individuals with cognitive limitations. The *Quality of Life Questionnaire* (QOL.Q; Schalock and Keith 1993) is a 40-item self-report interview designed to assess QOL in populations of individuals with intellectual and developmental disabilities. The QOL.Q consists of four subscales with 10 items per subscale: (1) satisfaction, (2) competency/productivity, (3) empowerment/independence, and (4) social belonging/community integration. The *Cross-Cultural Survey of Quality of Life Indicators* (Verdugo et al. 2005) is a related paper/pencil self-report survey for individuals with mild or moderate intellectual disability. A 4-point Likert scale is used to measure importance (*not important at all* to *very important*) and use (*never* to *always*) for 24 indicators across eight domains (emotional well-being, interpersonal relations, material well-being, personal development, self-determination, physical well-being, rights, and social inclusion). A recent analysis suggested that the measure represents three two-order factors: independence (comprising self-determination and personal development), social integration (comprising interpersonal relationship, rights, and social inclusion), and well-being (comprising emotional well-being, material well-being, and physical well-being; Wang et al. 2010).

Other QOL instruments draw on the perspectives and objective reports of others in the lives of

individuals with ASD (e.g., parents, caregivers) to assess QoL rather than employing self-reports of these individuals. These approaches may be especially salient when studying populations of children with ASD or adults with communication challenges. For example, Lee et al. (2008) assessed parent reported QoL for children with ASD utilizing items from the *National Survey of Children's Health*. This assessment includes items in the following areas: family burden, family outings (# times child taken on outing in past week), family meals (# of days in a week family ate together), religious service attendance, work disruption (did parent quit job b/c of child in past 12 months), days of missing school (0–3 scale for how often child missed school), activity participation (yes/no to any organizational involvement in past 12 months), repeated a grade (since kindergarten, yes/no), independence (did child spend time caring for him/herself in past week, yes/no), and community service (any service/volunteer activity in past 12 months, yes/no).

The *Overall Outcome Rating* (Eaves and Ho 2008) is a measure specific to ASD and is based on parental responses to interview questions in three domains: occupation, friendships, and independent living. Scores result in classifications of very good outcome (e.g., high level of independence, some friends, and a job), fair outcome, poor outcome, and very poor outcome (e.g., needing high level of care, no friends, and no autonomy). Notably, this measure does not assess subjective feelings/wishes of the person with ASD but rather the parent's assessment of life outcomes in more objective terms. As such, the Overall Outcome Rating is not technically a measure of life quality which ordinarily implies a subjective component as well as measuring outcomes.

Finally, the *Quality of Life Autism-Friendly Environment* was developed by Billstedt et al. (2011) and is unique, in that it focuses specifically on environmental features that reflect good quality of life for individuals with ASD. This measure includes ratings (1 = very good to 5 = very poor) of the environment in five areas: staff/caregivers have autism-specific knowledge, environmental structure, implementation of

specific treatment/training plans, match of activities to capacity, and overall quality of life.

Current Knowledge and Future Directions

When considering the current state of knowledge for the assessment of quality of life for individuals with ASD, it is clear that researchers are interested in utilizing careful measurement of quality of life not only to benchmark outcomes but also to understand what factors relate to a high quality of life for this population. Enhancing our understanding of what influences quality of life, at what times, and for whom, is critical for informing interventions and services to improve outcomes for individuals with ASD; the field is now beginning to answer these questions. Below we review the emerging literature on QoL for individuals with ASD, highlighting the individual characteristics and contextual factors that are associated with quality of life across the life course.

Findings regarding the influence of the characteristics of the individual with ASD in predicting QoL are mixed, with differences emerging depending on the constructs of focus and the study design. One of the strongest findings is that better adaptive behavior has been repeatedly linked with higher QoL in both children and adults with ASD (Bishop-Fitzpatrick et al. 2016; Kamp-Becker et al. 2010; Kuhlthau et al. 2010; Hong et al. 2016). However, intellectual ability and autism severity have not been consistently related to QoL (Kuhlthau et al. 2010; Kamp-Becker et al. 2010; Renty and Roeyers 2006). For example, in a study of QoL for adults with ASD older than 50 years, limitations in adaptive behavior difficulties and not autism per se were associated with poorer QoL (Totsika et al. 2010). Billstedt et al. (2011) similarly found that IQ, residential placement, and occupational activities were not predictive of QoL when utilizing their measure of “autism-friendly” environmental QoL. In contrast, Eaves and Ho (2008) found that higher childhood IQ and lower autism severity was associated with better overall outcomes during young adulthood when employing their rating

scale of “good” outcomes. These discrepancies are likely related to differences in the emphasis for the various measures employed in these studies (e.g., on subjective vs. objective appraisals).

Contextual factors have also been related to QoL. For example, higher perceived informal support and fewer unmet formal support needs were associated with higher QoL for adults with HFA (Renty and Roeyers 2006). Similarly, having regular recreational activities was associated with higher QoL in a sample of young adults with ASD (Billstedt et al. 2011). In contrast, negative experiences such as bullying and high levels of perceived stress have been linked with poorer quality of life based on adult self-report (Hong et al. 2016). Even during adulthood, the family context also appears to play a role in QoL, with maternal warmth acting as a predictor of QoL, above and beyond individual characteristics (Bishop-Fitzpatrick et al. 2016). Taken together, these findings suggest that individuals as well as their contexts contribute to their overall experience of QoL, with individuals with better adaptive functioning and more supportive environments having more optimal outcomes.

As we consider the next phase of quality of life research for individuals with ASD, there are several important areas of study. First, to date much research on QoL has utilized samples of convenience, often with exclusively male or primarily male respondents and often with few participants from racial, ethnic, or cultural minority groups. Given that most conceptualizations of QoL include a core emphasis on subjective appraisal, which can be deeply shaped by cultures values, identity, etc., understanding the intersections of disability, gender, and culture in defining, measuring, and predicting QoL for all individuals with ASD will be an important area for future research. Second, it will be valuable for future work to incorporate a range of quality of life indicators as outcome measures in intervention and services research. To do this, researchers will need to draw upon measures that are reliable and well-validated for individuals across the full autism spectrum and from multiple cultural groups; this may require additional validation studies for the development of new measures. Including targeted and relevant

QoL indicators in intervention research will be particularly important for understanding which services and supports can be leveraged to promote successful adaptation and healthy outcomes for individuals with ASD. Third, little is known about quality of life for adults on the autism spectrum as they enter later life. New research on aging in ASD is greatly needed. This work may similarly necessitate new research into the assessment of QoL, as our current self-report and parent report instruments may become less relevant or difficult to employ as individuals and their family members age (e.g., siblings may not be as reliable of reporters as parents – this remains to be tested). Finally, considerations of family quality of life, in combination with individual quality of life, continue to be needed. As noted above, some past work has utilized family-level benchmarks in the assessment of QoL, but this was for families of children. Consistent with family systems theory and ecological systems theory, individuals with ASD and their family members have linked life course trajectories. Measuring perspectives on QoL for multiple family members (and the subsequent interplay of stress, coping, and well-being among all family members) is important not only during the time surrounding diagnosis and the childhood years, but across the life course. In conclusion, in order to ultimately inform the implementation of services and supports that promote and maintain a high quality of life for all individuals with ASD, future work will need to continue to develop and confirm careful measures of multiple dimensions of QoL (across a range of individuals). By continuing to test theoretically-informed models of the individual and contextual factors, we will gain new understanding in what influences positive outcomes in the areas that matter most for these individuals and their families.

Assessment of Basic Language and Learning Skills (ABLLS)

Cheryl Smith Gabig

Department of Speech, Language, and Hearing Sciences, Lehman College/The City University of New York, Bronx, NY, USA

Synonyms

ABLLS-R; Assessment, curriculum guide, and skills tracking

Description

The Assessment of Basic Language and Learning Skills-Revised (ABLLS-R) is a criterion-referenced assessment tool, curriculum planning guide, and tracking system of requisite skills needed for basic language and communication development, as well as skills needed to support learning in important academic, adaptive, and motor areas. ABLLS-R provides a comprehensive review of 544 skills from 25 skill areas. The primary purpose of the ABLLS-R is to assess and identify skills in language/communication and critical academic learning, self-help, and motor areas in order to optimize communication, social interaction, and ongoing learning in everyday situations. A secondary purpose is to assist in determining and prioritizing educational objectives for an individual child. The ABLLS-R assessment can identify skills currently in the child's repertoire, the level of skill attainment, and allows for the ongoing tracking of progression in skill development.

The ABLLS-R is comprised of two separate documents: the ABLLS-R Protocol and the ABLLS-R Scoring Instruction and IEP Development Guide. The ABLLS-R Protocol is the assessment document that provides a task analysis of behaviors and skills in four areas: basic learner skills, academic skills, self-help skills, and motor skills. The basic learner skills assessment is the largest area of consideration and is comprised of

15 subcomponent skill areas including aspects of language and communication, imitation, visual learning ability, play and leisure, social skill interaction, group behavior, responding, and classroom functioning. Academic skill assessment includes task analyses for reading, math, writing, and spelling. The self-help skills assessed include dressing, eating, grooming, and toileting. The motor skills assessment addresses strengths and weaknesses in gross and fine motor abilities. The ABLLS-R Scoring Instruction and IEP Development Guide provide important information regarding scoring, prioritizing educational objectives, and developing an Individualized Education Program (IEP).

The ABLLS-R Protocol

Each language, communication, or learning area included in the ABLLS-R Protocol contains a list of underlying behaviors needed for potential mastery of the domain or skill area. The underlying skills for the domain are identified and numbered as tasks; each task has a corresponding task objective. Individual tasks can be directly observed or assessed for the child, and the level of skill attainment for the task objective determined by a score ranking. The numbered task items for each skill domain are presented in a visual grid display containing eight columns. The first column is the numbered Task, followed by the Score column, the Task Name column, the Task Objective column, the Question column to prompt recall or direct observation of the specific task item being assessed, an Examples column, the Criteria column specifying the standards for scoring, and a Notes column to record related information about the level of performance by the child on the task item. For example, for Task A1 under the skill area *Cooperation and Reinforcer Effectiveness*, the Score column shows a range of scores from 0 to 2, the Task Name states: *Takes reinforcer when offered*, the Task Objective states: *“When offered a known reinforcing item or activity, the students will take/use the item or activity,”* while the Question column provides the following question to prompt a recall or directly observe the requisite behavior: *“When you hold out and offer*

a known reinforcer, will the student take the reinforcer?” The Example column provides an exemplar of the desired behavior: *“M & M taken and eaten.”* The Criteria column specifies the standard that must be met for each of the numbered scores in the Score column: *2 = takes within 3 seconds all the time, 1 = either not all the time or takes more than 3 seconds to respond.*

For each task item in the ABLLS-R, the Score column has four rows of numbers. The initial assessment of the task item is scored in the first row; subsequent updates are scored successively in the rows below. The numbers included in the Score column range from zero to the highest possible score, which varies by task item as 1, 2, or 4. Therefore, depending on the task, the Score column may have four rows, each row with the numbers 0 1; 0 1 2; or 0 1 2 3 4. A score of zero is given when the skill is either absent from the child’s repertoire or the child does not meet the lowest criterion indicated in the Criteria column.

The ABLLS-R Scoring Instructions and IEP Development Guide

The Scoring Instructions and IEP Development Guide provides direction on the initial scoring, how to resolve discrepancies between reports about a specific skill, how to ensure the stability of scores, and how to transfer the scores from the initial assessment (or subsequent update) to the corresponding grid box on the skills tracking system sheets. The skills tracking grid is used by the educational support team, including the parents, teachers, and clinical staff to help determine the skill areas of need for each child and to develop a specific individual educational plan (IEP) for the child. The Scoring Instructions and IEP Development Guide also provides information about how to prioritize the needs of the child in order to develop an optimal IEP.

Historical Background

The ABLLS-R is an assessment and intervention planning tool based on the theory of verbal

behavior and learning of B.F. Skinner. Skinner proposed that language or verbal behavior is a product of an operant stimulus-response-reinforcement/punishment paradigm with additional consideration of the importance of aspects of stimulus control and motivation. Skinner's analysis of verbal behavior centered on a set of functional units called verbal operants; each verbal operant consists of the response or verbal behavior and its controlling antecedents and consequences. Skinner described four verbal operants related to vocal communication including echoic, mand, tact, and intraverbal. Each of these functional units is included in the basic learner skills assessment as vocal imitation, requests, labeling, and intraverbal, respectively. In addition to the functional verbal units, other important areas of cognitive development and behavior that affect verbal learning are included in the basic learner skills, including behaviors associated with motivation, the ability to attend to complex stimuli, generalization, the ability to use language without prompting, termed "spontaneity," the ability to quickly apply a learned verbal behavior, called fluency, joint attention, learner readiness, and social skills development.

The ABLLS-R Protocol and ABLLS-R guide are an update to the Assessment of Basic Language and Learning Skills (ABLLS), first published in 1998. The recent edition incorporates additional skills and two additional areas of importance to verbal learning and communication for children with autism not included in the initial publication. The two new areas include assessment of skill in joint attention and fluency. Fluency is the ability of a child to quickly apply and use a learned skill in a variety of contexts. Additional new items for specific areas were identified from the research literature on autism for inclusion in the 2006 edition, including new items added to the assessment of motivation, response to complex stimuli, generalization, learner readiness, social skills development, and imitation.

Psychometric Data

The ABLLS-R is a criterion-referenced assessment tool. As such, the ABLLS-R is not designed

to compare the child's skill or achievement to a standardized peer group. No age norms, standardized scores, or group comparison data are provided. The ABLLS-R provides a skills tracking system that targets the skill development in each area of assessment. The results can be displayed on a grid that visually portrays the level of functioning in each skill area assessed. The visual grid display allows for the easy identification of areas of significant or moderate deficit for use in identifying needed areas and skills for intervention. The ABLLS-R can be completed by a parent, educator, other professional, or a combination of these. The assessment can be done over a number of days or weeks, and each skill area can be revisited as the child progresses. Each assessment area has a number of task items identified to assess skill development and mastery of the area. The number of task items varies for each area assessed. For example, the receptive language area contains 57 tasks associated with the domain, whereas the vocal imitation domain contains 20 task items.

Clinical Uses

The ABLLS-R is useful for parents, educators, and special education support staff members to assess and identify specific skills needed by a child who is nonverbal or has significant speech and language delays. The ABLLS-R Protocol provides a careful analysis of needed skills that should be the focus of intervention. There are limitations to the ABLLS-R in that it is not an exhaustive list of skills needed, nor does it provide instructions for teaching a desired skill. The ABLLS-R is not standardized; therefore, a child's performance in an area cannot be compared to an age peer group.

[Activities of daily living \(ADLs\)](#); [Adaptive skills](#); [AFLS](#); [Criterion referenced assessment](#); [Functional living skills](#); [Self-help skills](#)

Description

The *Assessment of Functional Living Skills* (AFLS) is a criterion-referenced assessment used to measure essential skills throughout the lifespan for an individual (Partington and Mueller 2016). The AFLS is designed to assess the functional skill

repertoire of a learner across environments including home, school, community, and vocational sites. This comprehensive assessment is comprised of multiple modules that share consistent themes and foster overlapping goal development to increase an individual's learning and independence. For example, skills regarding meal preparation occur across environments throughout the assessment. These modules are represented in protocols which can be administered individually or in combination based on the current questions of the assessment team and characteristics of the individual being assessed (e.g., age, school placement, living arrangements). The ability to customize the assessment allows the evaluator to assess areas or domains that are pertinent to the individual at a given point in time (Partington and Mueller 2016).

The AFLS consists of a guide and six assessment protocols. The AFLS guide contains information about how to implement the assessment, what to teach and how to prompt skills, and task analyses to assist planning and programming. The protocols include assessments of *Basic Living Skills*, *Home Skills*, *Community Participation Skills*, *School Skills*, *Independent Living Skills*, and *Vocational Skills*. Collectively, these protocols assess of 1900 functional daily living skill in 66 skill areas (Partington and Mueller 2016).

AFLS Protocols. There are six assessment protocols included with the AFLS: *Basic Living Skills* (Partington and Mueller 2012a), *Community Participation Skills* (Partington and Mueller 2012b), *Home Skills* (Partington and Mueller 2012c), *School Skills* (Partington and Mueller 2013), *Independent Living Skills* (2015a), and *Vocational Skills* (2015b).

The *Basic Living Skills Assessment Protocol* (Partington and Mueller 2012a) evaluates eight general adaptive living skills that may be assessed across a variety of environments. The domains assessed include self-management, basic communication, dressing, toileting, grooming, bathing, health, safety and first aid, and nighttime routines.

The *Community Participation Assessment Protocol* (Partington and Mueller 2012b) assesses independence in a variety of community environments (e.g., grocery store, restaurants) across

eight domains including basic mobility, community knowledge, shopping, eat in public, money, phone, time, and social awareness and manners.

The *Home Skills Assessment Protocol* (Partington and Mueller 2012c) assesses eight essentials skill areas required for living in a home independently. The domains evaluated include meals at home, dishes, clothing and laundry, housekeeping and chores, household mechanics, leisure, kitchen, and cooking.

The *School Skills Assessment Protocol* (Partington and Mueller 2013) measures eight skill areas required to participate in school including routines and expectations including classroom mechanics, meals at school, routines and expectations, social skills, technology, common knowledge, core academics, and applied academics.

The *Independent Living Assessment Protocol* (Partington and Mueller 2015a) measures 16 skill areas necessary for an individual to live independent of supervision from others. The specific domains include organizational skills, self-care, maintenance and cleaning, mechanics and repairs, community travel, transportation, kitchen tools and appliances, food and meal planning, money management, independent shopping, personal management, safety, problem-solving, social interactions, and interpersonal relationships.

The *Vocational Skills Assessment Protocol* (Partington and Mueller 2015b) assesses 18 skill domains that are essential to acquiring a job as well as performing employment tasks including job search, interview, basic skills, co-worker relations, workplace safety, fixed activity skills, custodial and cleaning, laundry, retail, support personnel, office skills, computer skills, restaurant skills, restaurant kitchen, warehouse, tools, trades and construction, and landscaping.

Each protocol booklet is structured identically including a warning about learner safety when testing skills in potentially dangerous environments (e.g., crossing a street). The protocol booklets provide a brief overall of the *AFLS* assessment, information about the specific protocol, tracking grid to monitor progress for each

skill domain, and modules formatted in tables for each of the skill domains (Partington and Mueller 2016). For ease of use, each module is organized by broad skill domains, which are assigned a reference letter(s). For example, in the *Home Skills Assessment Protocol*, the broad skill area *Meals at Home*, is assigned the letters *MH*. Each individual skill is assigned a reference number that is combined with the domain reference letter(s). For example, the first skill in *Meals at Home* is referenced as item *MH1* (Partington and Mueller 2012c). The skill domain modules are organized similarly with the same headings. The first heading is *Task* which is the reference letter (s) and number for each item. The *Score* column is provided for the assessor to collect data by circling the number that corresponds to the learner's performance. The scoring numbers are presented horizontally in a row with either 0 1 2 or 0 1 2 3 4, which directly correspond to the specific score criteria in the *Criteria* column. The row of numbers is presented vertically four times so that each protocol booklet may be used across four separate scoring sessions. The next header, *Task Objective*, specifies the exact objective the individual must perform in order to receive a score. For example, the task objective for *MH1* is "Learner will identify finger foods versus non-finger foods" (Partington and Mueller 2012c, p. 1). The *Question* presents the objective in a question format which may be used when interviewing caregivers regarding the individual's ability to perform the skill. The *Example* header provides a specific scenario in which the individual should perform the skill. The *Criteria* header provides information regarding the number of targets, prompt levels, and other specific information needed in order to determine the overall quality of the individual's performance of the skill and directly corresponds to the scoring numbers in the *Score* column. A *Comment* column is provided in order to the evaluation to write in data collection and/or other anecdotal information that is important for the testing (Partington and Mueller 2016).

AFLS Guide. The *AFLS Guide* (Partington and Mueller 2016) is the user's manual for the

AFLS, and the information contained in the guide can be applied across all six protocols. The *AFLS Guide* opens with a statement regarding learner safety during across the testing period as many skills assessed may occur in environments in which safety should be a priority (e.g., kitchens, work areas with machinery and tools). Additional information found within the *AFLS Guide* includes an overview of the importance of teaching functional living skills, a review of specific terminology used within the *AFLS*, and a general overview of the *AFLS*. The *AFLS Guide* also contains implementation information for the assessors to follow during assessment periods. Further information located in the guide provides directions for determining which skills to teach, teaching methods, and recommendations for building a task analysis based on the outcomes of the assessment (Partington and Mueller 2016).

Historical Background

Prior to the development of the *AFLS*, James W. Partington and Mark L. Sundberg developed the *Assessment of Behavioral Language and Learning* (*ABLLS*; 1998) based on B. F. Skinner's *Verbal Behavior* (1957). Skinner described a stimulus-response contingency with regard to the development of verbal behavior, identified the speaker-listener relationship, and differentiated a behavioral approach to the development of communication that distinctly differs from traditional models of language development (1957). The *ABLS* (Partington and Sundberg 1998) and subsequently the *Assessment of Behavioral Language and Learning-Revised* (*ABLLS-R*; Partington 2010) established the first assessment for evaluating the basic language skills, social and group skills, and self-help skills for young learners on the autism spectrum and other developmental delays. The primary purpose of the *ABLLS-R* is to provide parents, teachers, and other caregivers a comprehensive method for assessing and tracking early developmental skills in order to guide the development of learning

objectives. The *ABLLS-R* assess 25 developmental domains that typically developing children master at approximately 4–5 years of age. While the *ABLLS-R* provides a foundational start for teaching language skills and learning readiness skills, the *ABLLS-R* is not a comprehensive assessment of independent living skills for young children and adults. Teaching adaptive and independent living skills across home, school, and the community is an essential component of educational plans for individuals with developmental delays. Therefore, Partington and Mueller developed the *AFLS* in order to meet the need for continued assessment of life skills across the age continuum (Partington Behavior Analysts 2016).

Psychometric Data

The *AFLS* is a criterion-referenced assessment and does not provide the standardized scores that accompany standardized assessments. As a criterion-referenced assessment, the *AFLS* provides information regarding the ability of the individual to perform specific skills identified as compared to the learner's previous performance across repeated testing (Powers et al. 2014). Each *AFLS* protocol is scored in the same manner. For every task, evaluators circle the score that corresponds to the learner's current level of performance based on the criteria specified in the protocol. A score of zero indicates a task the learner is unable to perform or does not meet the criterion for the lowest score associated with that task (Partington and Mueller 2016). Skills that may never be applicable or may not be applicable for that learner at the time of the assessment may be scored as not applicable. Specific information regarding the skills can be noted in the comment section for each task. The scores are represented in a tracking grid that corresponds to the specific protocol assessed. The protocol allows for the assessment to be updated three times for each learner. The tracking grid should be marked differentially, using a different color for updates. The use of different colors allows for assessors,

parents, school personnel, and others to visually analyze the learner's progress and skill growth across subsequent reevaluations (Partington and Mueller 2016).

Clinical Uses

The *AFLS* measures and tracks a learner's current level of functioning across a variety of skills that are essential for living and participating in the home, school, community, and vocational settings (Partington and Mueller 2016). The *AFLS* may be completed by school professionals, caregivers, and community service providers to assess a learner's level of independent functioning across a variety of settings. The three primary sources of information required to complete the *AFLS* assessment include interviews of caregivers, direct observation/testing, and/or historical data. Assessors gather information from caretakers who regularly interact, directly observe, and formally present tasks to the learner (Partington and Mueller 2016).

of Texas at El Paso College of Health Science,
El Paso, TX, USA

Synonyms

[Augmentative and alternative communication \(AAC\) device](#)

Definition

Assistive devices are aided communication systems used in the area of augmentative and alternative communication (AAC). Aided systems are ones that require something other than the individuals' body to communicate. That "something" could be picture symbols, written words, or a high-tech speech-generating device. Conversely, unaided systems are those that do not require anything separate from one's own body to communicate. Essentially, gestures, body language, and sign language are examples of unaided systems. Examples of assistive devices are individual picture symbols, picture communication boards, mid-tech communication aids such as the MessageMate (sold by Words+), and high-tech communication devices such as the VMax (sold by DynaVox). See Beukelman and Mirenda (2005) for a detailed description of assistive devices and their implementation.

Association for Retarded Citizens (Arc)

Peter Doehring
Foundations Behavioral Health, Doylestown, PA,
USA
ASD Roadmap, Chadds Ford, PA, USA

Major Areas or Mission Statement

The mission of The Arc is to "promote and protect the human rights of people with intellectual and developmental disabilities and actively supports their full inclusion and participation in the community throughout their lifetimes."

Landmark Contributions

The Arc was founded in 1950 as the National Association of Parents and Friends of Mentally Retarded Children. It initially focused on changing perceptions about I/DD (then referred to as mental retardation), from the assumption that most persons with I/DD necessitated institutionalization, to the recognition of their potential and their rights to employment and education. During the 1960s and 1970s, The Arc advocated for key legislation, including the passage of Public Law 94-142 (guaranteeing a free and appropriate education to children with disabilities) and legislation to create the Supplemental Security Income program to support persons with

disabilities. Since that time, The Arc has contributed significantly to efforts to pass many other laws contributing to increased community-based options for living (e.g., the creation of Medicaid-funded home and community-based waivers) and working (e.g., incentives for employers who hire persons with disabilities), other initiatives related to health (e.g., Medicaid's Early and Periodic Screening, Diagnosis, and Treatment program), and the landmark Americans with Disabilities Act.

The Arc has also contributed to the scientific understanding of I/DD. In the 1960s, The Arc helped to first expose links between lead poisoning and brain damage in children. Research and other work funded by The Arc in the 1970s helped to identify the treatment for phenylketonuria (PKU), to define Fetal Alcohol Spectrum Disorder, and to first suggest infant undernutrition as a cause of developmental disabilities. Since that time, The Arc also began to support the dissemination of scientific findings through its sponsorship or organization of key summits and publications.

Major Activities

The Arc describes itself as “the largest national community-based organization advocating for and serving people with intellectual and developmental disabilities and their families. We encompass all ages and all spectrums from autism, Down syndrome, Fragile X and various other developmental disabilities.” The Arc actively contributes to the development of public policies at the local, state, and federal level.

Education and Activism is a core activity of The Arc at the local, state, and federal level levels, in support of legislation for civil rights, education, employment, health care, housing, and other areas of interest. With funding from Administration on Developmental Disabilities, The Arc recently established the National Autism Resource and Information Center as a “central point of access to high-quality and evidence-based resources and information for individuals with Autism Spectrum Disorder (ASD) and other developmental disabilities, their families, professionals, and other targeted key stakeholders, including underserved and unserved.”

A broad range of supports and services are also offered by individual chapters of The Arc, including information and referral, advocacy and self-advocacy around a broad range of issues, residential support, family support, employment programs, and leisure and recreational programs.

In 2011, The Arc had more than 700 state and local chapters, and more than 140,000 members across the United States. Members come from all walks of life, though most are family members or persons with intellectual and developmental disabilities (I/DD).

Associative Learning

Rebecca DeAquir

The Center for Children with Special Needs,
Glastonbury, CT, USA

Definition

Associative learning refers to the process in which a new response is paired with a particular stimulus or response that already exists within the learner's repertoire or experiences; it is based on the ideas that experiences reinforce one another and can be linked to enhance the learning process. Associative learning responses are “associative” in that the responses being learned are associated with previous responses or stimuli, either conditioned or unconditioned. Associative learning, like classical conditioning, involves pairing an unconditioned stimulus (which reflexively produces a response) with another stimulus that is neutral. Over time, the pairing results in the reliable emission of a response that was previously not consistently emitted.

Ataxia

Fred R. Volkmar

Child Study Center, Irving B. Harris Professor of Child Psychiatry, Pediatrics and Psychology, Yale Child Study Center, School of Medicine, Yale University, New Haven, CT, USA

Synonyms

[Dystaxia](#)

Definition

Unsteady gait. The term ataxia refers to lack of coordination of motor movements. Ataxia typically arises due to some dysfunction within the central nervous system. It has many different causes, e.g., it can be a sign of dysfunction in the cerebellum (where it usually would be associated with various other difficulties). Other causes can relate to effects of drugs or other substances and problems with the vestibular system and other parts of the brain. Medications given to control seizures are a common cause of ataxia; abuse of some substances (e.g., alcohol) may also lead to ataxia.

Ataxia can also arise as a result of a deficiency in vitamin B₁₂, exposure to certain toxic agents, and so forth. Problems in the peripheral nervous system can also be associated with ataxia. Certain inherited (genetic) disorders can also lead to ataxia.

In autism, problems in posture and gait are relatively common. Problems with clinically significant ataxia often are associated with drug treatments (e.g., for seizures). In Rett's disorder, ataxia and other movement problems are quite common and associated with the underlying pathophysiology of the condition.

Treatment varies depending on the cause. Physical therapy can be useful in some cases, and some drug treatments have also been proposed.

Atomoxetine

D. O. Alvi Azad

Yale Child Study Center, The Edward Zigler
Center in Child Development and Social Policy,
Yale University, New Haven, CT, USA

Synonyms

[Strattera \(TM\)](#)

Definition

Atomoxetine is a drug approved for the treatment of attention-deficit hyperactivity disorder (ADHD). This compound is manufactured, marketed, and sold in the United States under the brand name Strattera by Eli Lilly and Company. Generics of atomoxetine are sold in other countries.

Clinical Use

Atomoxetine is approved for use in children, adolescents, and adults; however, its efficacy has not been studied in children under 6 years old. Its advantage over stimulants for the treatment of ADHD is that it has less abuse potential than stimulants (Wee and Woolverton 2004), is not scheduled as a controlled substance, and has shown in clinical trials to offer 24-h coverage of symptoms associated with ADHD in adults and children (May and Kratochvil 2010).

Therapeutic effects of atomoxetine may take a week to be felt and an adequate trial may be up to 8 weeks (May and Kratochvil 2010). Many people respond to atomoxetine who do not respond to stimulants (May & Kratochvil). Atomoxetine may be preferred over amphetamine-based stimulants in patients with psychiatric disorders, those who cannot tolerate stimulants, and those with a substance misuse recurring history. Therapy is

usually initiated by gradually increasing the dose to minimize side effects.

Arnold et al. in 2006 enrolled 16 pediatric patients with pervasive developmental disorder (PDD) in a double-blind, placebo-controlled, crossover study and found that 57% of the pediatric patients responded to atomoxetine (Arnold et al. 2006).

Mechanism of Action

Atomoxetine acts by selectively blocking the norepinephrine transporter. The norepinephrine transporter takes up norepinephrine as well as dopamine in the prefrontal cortex, with little to no activity at the other neuronal reuptake pumps or receptor sites. Blocking the norepinephrine transporter increases norepinephrine as well as dopamine levels; this mechanism was studied in rat prefrontal cortices (Bymaster et al. 2002). Atomoxetine has been shown to improve prefrontal cortices in normal adults with ADHD (Chamberlain et al. 2006, 2007).

Dosing

Once- or twice-daily atomoxetine was effective in the short-term treatment of ADHD in children and adolescents, as observed in several placebo-controlled trials (May and Kratochvil 2010), 0.5–1.4 mg to kilogram of body weight (May & Kratochvil).

Side Effects

The side effects include dry mouth, tiredness, irritability, nausea, decreased appetite, constipation, dizziness, sweating, dysuria, sexual problems, increased obsessive behavior, weight changes, palpitations, and increases in heart rate and blood pressure (Chamberlain et al. 2006).

Two confirmed cases of liver injury have been reported by Eli Lilly and Company out of

approximately two million prescriptions written. In both cases, upon discontinuation of atomoxetine, patients' liver functions returned to normal (Chamberlain et al. 2006).

There is a black box warning for increased risk of suicidality in children and adolescent with ADHD especially during the first month of treatment.

Pharmacology

Pharmacokinetic data: bioavailability, 63–94%; protein binding (primarily albumin), 40%; metabolism, hepatic, via CYP2C19 (minor), 2D6 (major) (Garnock-Jones and Keating 2009).

Bioavailability: 63% in extensive metabolizers; 94% in poor metabolizers (Garnock-Jones and Keating 2009).

Half-life elimination: atomoxetine: 5 h (up to 24 h in poor metabolizers); active metabolites, 4-hydroxyatomoxetine: 6–8 h; N-desmethylatomoxetine: 6–8 h (34–40 h in poor metabolizers) (Chalon et al. 2003; Witcher et al. 2003).

Time to peak, plasma: 1–2 h (Chamberlain et al. 2006).

Excretion: Urine (80%, as conjugated 4-hydroxy metabolite); feces (17%) (Chamberlain et al. 2006).

Attachment

Nirit Bauminger-Zviely

School of Education, Bar-Illan University, Ramat-Gan, Israel

Definition

According to Bowlby (1969/1982), attachment constitutes the first affective bond that the child forms with the primary caregiver. Bowlby, drawing from object relations theory, suggested that in the first year of life it is in the infant's interest to seek out proximity to the attachment figure when under stress (Bretherton 1985). Thus, to foster proximity, the child and mother are involved in many interactions. According to Bowlby, the

responsiveness of the mother to the child's signals will determine the nature of their relationship, which the child will internalize via working models. The working model comprises the representation of the child's knowledge about the world and about significant persons in the world, including the self (Bowlby 1969/1982). These models are useful in guiding behaviors in new situations. Furthermore, they affect the quality of the child's future relationships throughout life (Sroufe and Fleeson 1986). Once working models are established, they tend to remain stable. The "marker behaviors" of attachment can change throughout stages of child development (e.g., physical proximity or checking in with mother in the first years, verbal negotiation at age 3 or 4). However, the construction of the attachment patterns (secure or insecure) tends to remain stable (Bretherton 1985).

The perception of attachment as an affective bond means that the child is forming long enduring ties with noninterchangeable "significant other/s" (Ainsworth 1989). Thus, the infant's initial ability to differentiate between people and inanimate objects and then the capacity to distinguish the primary caregiver from other individuals are precursors to the ability to form attachment. On the basis of these differentiations, the child directs more proximity-seeking behaviors toward the primary caregiver, shows more distress in the caregiver's absence, and calms down in the caregiver's presence. Behaviors maintaining proximity during infancy include active efforts to stay close to the mother (e.g., approaching, following, clinging) and signaling behaviors (e.g., smiling, crying, calling) (Ainsworth et al. 1978).

A child might be able to differentiate between the mother and other individuals yet nevertheless form an insecure attachment with the mother. Thus, the quality of attachment also needs to be considered. The "strange situation" paradigm, a series of eight episodes in which the infant is given the opportunity to interact with an unfamiliar adult in the mother's presence and absence, was developed to identify individual differences in children's quality of attachment (Ainsworth et al. 1978). The child's reactions to the separation and reunion with the mother during the "strange

situation" episodes enable classification of children as either securely attached to their mothers (e.g., showing distress at separation and attempting to reestablish interaction at reunion) or as insecurely attached. Insecure attachment can be "avoidant" (e.g., showing indifference at separation and actively avoiding parents at reunion), "resistant/ambivalent" (e.g., presenting high distress at separation and responding to reunion with mixed feelings of rejection and approaching), or as later identified by Main and Solomon (1986, 1990), "insecure/disorganized" (e.g., lacking observable goals, intentions, or explanations in the parent's presence, such as stereotypical movements or misdirected and incomplete expressions).

Synonyms

Disinhibited attachment disorder; Disinhibited social engagement disorder; Emotionally withdrawn/inhibited attachment disorder; Indiscriminate friendliness; Indiscriminate sociability; Indiscriminate social behavior; Indiscriminately social/disinhibited attachment disorder; Reactive attachment disorder

Short Description or Definition

Attachment disorders describe aberrant social behaviors in young children, particularly regarding how and from whom they seek comfort, support, nurturance, and protection. Two major types have been defined, an emotionally withdrawn/inhibited type, in which the child lacks social and emotional responses, and an indiscriminately social/disinhibited type, in which the child lacks social wariness about unfamiliar adults. The former includes the absence of attachment behaviors directed at caregivers, while the latter refers to social behaviors directed at unfamiliar adults.

Categorization

DSM-IV-TR (American Psychiatric Association [APA] 2000) describes two subtypes of reactive attachment disorder, an emotionally withdrawn/inhibited type and an indiscriminately social/disinhibited type, whereas ICD-10 (World Health Organization [WHO] 1992) defines “reactive attachment disorder” as the emotionally withdrawn/inhibited type and “disinhibited attachment

disorder” as the indiscriminately social/disinhibited type. Recent reviews have concluded that these types actually represent two distinct disorders that share primarily the conditions of risk in which they each occur (Rutter et al. 2009; Zeanah and Gleason 2010). For this reason, DSM 5, in keeping with ICD-10, is proposing to define two distinct disorders.

The emotionally withdrawn/inhibited type of reactive attachment disorder is characterized by a child who appears emotionally unresponsive with limited or no positive affect. These children do not have much of an interest in interaction with any adult, and social reciprocity is minimal or absent. This overt apathy toward relationships extends to the attachment relationship. These children do not exhibit consistent or robustly developed attachment behaviors, that is, behaviors that promote proximity to preferred adults. Children with emotionally withdrawn/inhibited RAD fail to check in with familiar adults, and they neither seek nor accept comfort from caregivers in times of emotional need.

In contrast, children with the indiscriminately social/disinhibited type of reactive attachment disorder are overly familiar, even with adults they do not know. They can be intrusive and lack appropriate social and physical boundaries, as well as emotionally “over bright” and attention seeking. They lack reticence around unfamiliar adults, instead approaching and engaging with anyone. In fact, they are notably willing to “go off” with complete strangers. They may be aggressive as well as uncomfortably “friendly.”

Epidemiology

These disorders are believed to be rare, even in clinic-referred children, but epidemiological data are scarce. In a quasi-epidemiologic study (Egger et al. 2006), for example, 300 children were recruited from pediatric clinics, but there were no cases of reactive attachment disorder identified. A cohort study by Skovgaard showed a prevalence of 0.9% of attachment disorders. In a study of young children with a history of varying

amounts of institutional rearing (range of 6–54 months), only 10% had a diagnosis of RAD at 54 months of age, though a majority of children showed subthreshold signs of the disorder (Gleason et al. 2011). Thus, although signs of the disorder may be evident in children with histories of maltreatment (Pears et al. 2010; Oosterman and Schuengel 2007; Zeanah et al. 2004) or institutional rearing (Chisholm 1998; Gleason et al. 2011; Rutter et al. 2007; Tizard and Rees 1975; Zeanah et al. 2005), children meeting full criteria for the disorder are rare, especially if they are living in families.

Natural History, Prognostic Factors, and Outcomes

Since most children who are severely neglected or raised in deprived institutions do not develop attachment disorders, there must be vulnerability factors that predispose children to one or the other types of RAD. Little progress to date in elucidating those factors has been made. A related question is why children who share risk factors of neglect and deprivation develop such distinctively different phenotypes – one withdrawn and unresponsive and the other overly bright emotionally and attention seeking. Again, there have been no published studies to date that have addressed these issues. Temperamental differences or genetic polymorphisms are potential vulnerability factors.

One of the hallmark features of attachment disorder is that they are supposed to be responsive to changes in the caregiving environment. This is quite clear in the case of emotionally withdrawn/inhibited RAD, but less clear in the case of indiscriminately social/disinhibited RAD as illustrated in the following two examples.

Case 1

Cade is a 30-month-old boy who spent the first 20 months of his life in a run-down apartment. His mother had a serious substance use disorder, which became worse after he turned a year old.

Only rarely did she have someone watch him. Instead, she often left him on the floor in the kitchen, with a bowl of dry cereal, and a pet gate in place so that he would not leave the kitchen. A neighbor called the police, and Cade was taken into State's custody.

Cade was found to be malnourished, but he quickly recovered physically. Most striking about his behavior in the foster home was his eagerness to be held by everyone. He immediately approached any adult, and he showed no preferences nor any reticence. He seemed starved for attention, and his affect was overly bright. Because his mother surrendered her rights to him, Cade was adopted when he was 28 months old. With his adoptive parents, he continued to display intrusive, affectionate behavior. They were concerned because he continued to go readily to any stranger.

They were counseled to restrict his contact with adults other than the two of them for several months. Following this, he began to seek comfort preferentially from his foster parents when he was distressed and to protest when they left him. They felt that he became increasingly affectionate with them. Despite these gains, after several months when they began to take him into public, he still showed occasional lack of reticence with strangers, and they feared that he would be willing to go off with one.

Case 2

Zoe was taken into State's custody when she was 13 months old because of neglect and concerns about her safety. Zoe's mother had been displaying increasingly bizarre behavior, according to the records, and she was later diagnosed with schizophrenia. She wanted to protect and care for Zoe, so she put her in a crib in the closet for hours at a time "to keep her safe." She did not like Zoe being around people because she was afraid of their germs. She refused to take Zoe to the physician because of all of the "sick people" there. Zoe was removed by Child Protective Services and placed in her paternal grandmother's care. She spent her initial days there staring at

the wall or idly touching toys. Her grandmother described her blank stare as “unnerving.” Zoe was easily frustrated and difficult to console. At times, she smiled but her smile had a frozen, empty quality and did not convey any sense of authentic positive affect. Her grandmother described Zoe as “stiff and awkward to hold.” Zoe seemed to be fine as long as she was left alone.

After a few weeks of being in her grandmother’s care, Zoe improved substantially. She began to interact reciprocally with her grandmother, and she ran to her when she wanted comfort. She was easily consoled, but only by her grandmother. She clung tightly to her grandmother when a stranger came into the room. Her frozen smile disappeared, and she readily conveyed moments of genuine enjoyment, though she remained irritable and easily frustrated for several more months.

In studies of children adopted out of institutions, there have been no children identified with emotionally withdrawn/inhibited RAD in follow-ups months to years later (Chisholm 1998; Rutter et al. 2007; Hodges and Tizard 1989). Similarly, in the Bucharest Early Intervention Project (BEIP), children removed from institutions and placed in foster care had a strong and early reduction in signs of emotionally withdrawn/inhibited RAD compared to children who remained institutionalized (Smyke et al. 2012). In other words, once children are removed from socially depriving environments of institutions and are placed with families, signs of emotionally withdrawn/inhibited RAD disappear. On the other hand, for children who remain in institutions, signs of emotionally withdrawn/inhibited RAD are moderately stable over time (Gleason et al. 2011). Thus, when being raised in environments in which opportunities to form selective attachments are limited, children may manifest signs of emotionally withdrawn/inhibited RAD. However, they tend to recover when placed in more normative environments.

The findings regarding the course of indiscriminately social/disinhibited RAD are somewhat different. The stability of indiscriminate behavior is modest to moderate, in both institutionalized (Gleason et al. 2011) and formerly institutionalized

children (Rutter et al. 2007). Both short-term (Chisholm 1998; Gleason et al. 2011) and long-term (Hodges and Tizard 1989; Rutter et al. 2007) longitudinal studies have shown that indiscriminate behavior, once present, is quite persistent in a minority of children who were raised in institutions, even if they are later adopted or placed with families. Indiscriminate behavior that persisted into adolescence was associated with peer problems. Furthermore, in the Bucharest Early Intervention Project, reduction in signs of indiscriminate/disinhibited RAD was less powerful than the reduction in signs of emotionally withdrawn/inhibited RAD following placement in families (Gleason et al. 2011).

Prognostic factors are not well delineated among children with attachment disorders. Generally, the sooner that a young child can be placed within a loving environment the better, but the long-term outcomes of children diagnosed in early childhood with attachment disorders is not well delineated. Signs of both emotionally withdrawn/inhibited and indiscriminately social/disinhibited RAD in children less than 30 months of age were predictive of overall psychiatric impairment at 54 months (Gleason et al. 2011). Still, little is known about individual differences in prognosis.

Clinical Expression and Pathophysiology

Attachment describes a tendency for human infants to seek comfort, support, nurturance, and protection from one or more discriminated caregivers. The tendency for selective seeking of comfort is not apparent at birth, however. Following a period of interaction and comfort with adult caregivers during the first 6 months, two new infant behaviors become apparent at around 7–9 months of age, stranger wariness and separation protest. Stranger wariness describes an apparent discomfort with unfamiliar adults and selectively turning to those the child knows and trusts. Separation protest refers to the infant’s tendency to protest separation from familiar caregivers. Although individual differences in the intensity and expression of these behaviors are clear, they seem to be

universal. When these behaviors appear, the infant is said to be attached to one or more caregivers.

Under species typical rearing conditions, virtually all infants seem to become attached, generally to a relatively small number of caregiving adults with whom they have regular and substantial contact. Once infants reach a cognitive age of 7–9 months, they begin to seek comfort, support, nurturance, and protection from a relatively small number of caregiving adults whom they have learned through repeated experiences are available to them. Research has demonstrated clearly that the quality of infants' attachments to one or more caregivers is predictive of subsequent psychosocial adaptation. Security of attachment has been measured categorically and continuously and predicts subsequent adjustment, particularly in high-risk groups of children.

In extreme rearing conditions; however, such as social neglect or institutional care, attachment may be seriously compromised or even absent. Attachment disorders describe a constellation of aberrant attachment behaviors and other behavioral anomalies that are believed to result from social neglect and deprivation. For this reason, RAD requires a history of "pathogenic caregiving." In response, rather than insecure attachments, young children with attachment disorders display absent or serious aberrations of attachment. Two clinical patterns, described above, have been defined: an emotionally withdrawn/inhibited pattern and an indiscriminately social/disinhibited pattern. In the emotionally withdrawn/inhibited pattern, the child exhibits limited or absent initiation or response to social interactions with caregivers and aberrant social behaviors, such as constricted, hypervigilant, or highly ambivalent reactions. In the indiscriminate pattern, the child exhibits lack of expected selectivity in seeking comfort, support, and nurturance, with lack of social reticence with unfamiliar adults and a willingness to "go off" with strangers.

What is striking about children with the emotionally withdrawn/inhibited RAD is that they have minimal or no signs of attachment to caregiving adults. The lack of selective attachments in children cognitively capable of forming attachments is the essence of the disorder. In contrast,

children may exhibit signs of indiscriminately social/disinhibited RAD whether or not they have formed attachments. The essence of this form of the disorder is socially disinhibited behavior with strangers. Because it has been documented in children with healthy and unhealthy attachments, as well as in children with no attachments, some have suggested that it is not actually an attachment disorder. For this reason, the current DSM 5 proposal is to define it as disinhibited social engagement disorder, distinct from RAD (Zeanah and Gleason 2010).

Evaluation and Differential Diagnosis

In order to assess the presence or absence of attachment in a child, it is necessary to evaluate the relationship of the child with each of her caregivers. A child is able to have different types of attachments with each of her caregivers. Knowing about a child's attachment to one caregiver does not reveal anything about the child's attachment to another caregiver, and not being attached to one caregiver does not mean that the child is not attached to another caregiver. Thus, the child should be seen with different caregivers in order to assess the lack of attachment that is necessary to make the diagnosis of emotionally withdrawn/inhibited RAD.

The first step in the evaluation is to gather a thorough history of the child. This history should include information on the child's current behaviors, past behaviors, social history, developmental history, medical history, and family history. Careful attention to the emergence and expression of selective attachment behaviors is important.

To guide diagnosis of attachment disorders, use of a structured interview with the child's caregiver, such as the Disturbances of Attachment Interview (Gleason et al. 2011), may be useful. This interview systematically inquires about signs of emotionally withdrawn/inhibited RAD, indiscriminately social/disinhibited RAD, and other aberrant attachment behaviors expressed toward caregivers. For children who have experienced pathogenic or grossly inadequate care, identifying a reporter who is knowledgeable about the child's behaviors may be a challenge.

The evaluation of the child should include inquiries about the child's behavior in different settings and with different caregivers to note any differences. Formal observations of the child and parent interactions are also important. Procedures derived from developmental research, such as the Strange Situation Procedure (Ainsworth et al. 1978) or the Crowell procedure (Zeanah et al. 2000), are relatively short observations of child and parent interaction which help the clinician systematically to observe the interaction between the child and caregiver (Zeanah et al. 2011).

During the assessment, there are several other diagnoses to consider since attachment disorders may share features of some other disorders (see Table 1 for details). For example, emotionally withdrawn/inhibited RAD may be confused with autistic spectrum disorders or global developmental delay. The problems with emotional regulation and impaired social reciprocity may resemble the social difficulties of a child with an autistic spectrum disorder. On the other hand, there is little reason to expect restricted interests or repetitive behaviors in children with attachment disorders. A history of adverse caregiving as well as no selective impairment in language or pretend play should point toward a diagnosis of RAD in such

children. Although children with RAD are likely to have cognitive delays, their impaired social responsiveness is not a symptom of intellectual disabilities alone. Children with intellectual disabilities should have social behavior and emotional expressiveness congruent with their cognitive ages. On the other hand, selective reductions in social reciprocity and emotional expressiveness are more indicative of emotionally withdrawn/inhibited RAD.

An important diagnosis to consider with indiscriminately social/disinhibited RAD is attention deficit hyperactivity disorder (ADHD). In RAD, young children have social impulsivity, but this should not be confused with the broader impulsivity and hyperactivity of children with ADHD. It is important to look in detail at how the child interacts in social situations and especially with unfamiliar adults. Children with RAD lack selectivity in directing their social and sometimes attachment behaviors. Children with ADHD may share these features but also demonstrate impulsivity in nonsocial situations. Children with indiscriminately social/disinhibited RAD should show more profound misreading of social cues and situations and engage in more social and physical boundary violations.

Attachment Disorder, Table 1 Differential diagnosis of attachment disorders

Attachment disorder	Differential diagnosis	Similarities	Differences
Emotionally withdrawn/inhibited type	1. Autistic spectrum disorder	1. Disturbances in emotional regulation	1. Attachment disorder does not have selective impairment in pretend play, repetitive preoccupation, or a language abnormality
		2. Impaired or absent social and emotional reciprocity	2. Attachment disorder has a history of seriously adverse caregiving
		3. May involve cognitive delays	
Emotionally withdrawn/inhibited type	1. Intellectual disability	1. Cognitive delays	1. Attachment disorder does not have social/emotional behaviors consistent with developmental age
			2. Attachment disorder has evidence of deviance in social responsiveness and regulations of emotion
Indiscriminately social/disinhibited type	1. Attention deficit hyperactivity disorder	Social impulsivity and attention seeking behavior	1. Attachment disorder in males shows a lack of selectivity in relationships with caregivers and peers

Treatment

There is only one intentional treatment study of attachment disorders that includes pre- and post-assessments and uses random assignment (Smyke et al. in preparation). The BEIP demonstrated substantial treatment effects on reduction of signs of emotionally withdrawn/inhibited RAD and more modest treatment effects of reduction in signs of indiscriminately social/disinhibited RAD for children placed in foster care compared to those who experienced continued institutional care (Smyke et al.). This study bolsters confidence in other less rigorously designed studies that all suggest that signs of emotionally withdrawn/inhibited RAD disappear rapidly when children are placed in reasonably normative caregiving environments. Similarly, the results in BEIP are compatible with studies of internationally adopted children suggesting that signs of indiscriminately social/disinhibited RAD are less responsive to more normative caregiving environments, and that a minority of children have persistent signs of the disorder over years (Smyke et al.).

Future research needs to better determine recommendations for adoptive parents whose young children exhibit signs of RAD and how best to deal not only with the behavioral manifestation but also with the social cognitive abnormalities that presumably underlie the disorder. Further, although there is a clear tendency for signs of both types of disorders to diminish over time, questions about sequelae have not been adequately answered at this point.

Definition

The ability to orient, sustain, and shift attention on relevant stimuli, using internal and external cues, is a critical skill for learning about the world. Prioritizing stimuli in order to process pertinent, and exclude peripheral, information facilitates selective learning, a skill necessary for many child development processes, including vocabulary development, problem solving, and later, successful classroom learning (Frick and Richards 2001; Kannass and Colombo 2007; Sillar and Sigman 2008). Children with autism often display

atypical development of attention. The processes in which these abnormalities manifest, however, are yet to be determined (Ames and Fletcher-Watson 2010). Despite the high prevalence of attentional difficulties seen in children with autism, these difficulties are not considered a core characteristic of the disorder as specified by the fourth version of the Diagnostic and Statistical Handbook of Mental Disorders (DSM IV 1994), but rather an associated symptom of ASD.

Behavior is acted upon using visual information from the environment. For example, safe driving is largely dependent on drivers attending to stoplights, signs, pedestrians, and other cars and ignoring distracting, irrelevant environmental stimuli. The breadth of attention literature identifies several components of domain-specific and domain-general attending. Visual attention, in particular, plays a large role in domain-specific attention, such as social attention. Social attention is the preferential selection of social over nonsocial stimuli for attention and has been the subject of much research due to its high correlation with later social developmental processes, such as joint attention, theory of mind, and language development (Adamson et al. 2009; Ames and Fletcher-Watson 2010; Mundy and Newell 2007; Sodian and Thoermer 2008). Moreover, social attention is of particular interest to the study of autism due to its relation to social interactions and communication, two core deficits of the disorder.

Attention may be subdivided into the ability to focus, sustain, shift, and encode (Goldstein et al. 2001; Zubin 1975). Focused attention is the ability to concentrate and perform a task on a specific stimulus in the midst of distracting stimuli. Sustained attention is defined as the capacity to maintain attention on a target stimulus over a prolonged period of time. Shifting attention is the ability to effectively transfer concentration from one stimulus to another. Encoding attention is the ability to intake and interpret information from the environment (Goldstein et al. 2001). Research on these specific skills may be used to identify which aspects of attention children with autism seem to struggle with most and, conversely, which areas of attention develop typically.

A comprehensive understanding of attention must include a description of environmental stimuli that help an individual to attend. Attention cueing, that is, attention directed by environmental prompts, affects what stimuli humans attend to; these environmental prompts are identified as exogenous and endogenous factors. Exogenous cues, those that activate “bottom-up” processes, are derived from stimuli properties (e.g., size, color) and evoke involuntary attention (Corbetta and Shulman 2002). Endogenous cues, on the other hand, often characterized as activating “top-down” processes, evoke conscious and voluntary attention control through cognitive processes, learned behavior, or past experiences (Corbetta and Shulman 2002; Hauer and MacLeod 2006). In this way, previous experiences and learned behaviors influence on what or where the child attends.

The multitude of cognitive, social, and language developmental skills learned during play make free play an important setting in which to study attention in children. Ruff and Capozzoli (2003) studied the developmental trajectory of visual attention during play and identified three types of attention. Causal attention is defined as looking at objects (e.g., toys), but not physically engaging with them; settled attention is looking at and manipulating an object; and focused attention is concentrating on an object intently and may include facial expressions and extraneous body movement in order to bring the object closer to the face or body. Collectively, the study of attention covers a wide array of specific topics, all of which hold importance for a comprehensive understanding of the topic and for the development of interventions aimed at healthy development.

Historical Background

Attention has been a topic of study for decades by researchers and clinicians alike. Because of the high occurrence of attention deficits in autism, this topic has been the focus of numerous studies in autism research, in particular. The discourse of processes and causes of this apparent attention

deficit has evolved over time. Early researchers hypothesized that attention difficulties in children with autism were due to hypo- or hyperarousal. That is, some researchers concluded that arousal modulation in particular, was a potential cause of low attention abilities (Hutt et al. 1964; Ornitz and Ritvo 1968). Other investigators attributed limited attention skills to over-selectivity or what some referred to as “tunnel vision,” that is, intense attention to specific details in combination with a lack of interpretation of outside environmental cues (Lovaas et al. 1979; Rincover and Ducharme 1987). More recently, it has been hypothesized that attention problems may be due to difficulties in prioritizing relevant stimuli and disregarding irrelevant stimuli (Bryson et al. 1990; Burack 1994). Furthermore, Ornitz and colleagues (1988) proposed that children with autism struggle in attention shifting, in particular, because they lack an interest in people or social stimuli (Ornitz 1988). Previous studies have also dichotomized attention in studying auditory and visual attention and found that children with autism differed from typical children in auditory attention (Casey et al. 1993) but not in visual attention (Pascualvaca et al. 1998). This finding, however, is inconsistent with more recent findings concerning visual attention in the literature (Goldstein et al. 2001; Leekam et al. 2000) and may be due to differences in measurement (Ames and Fletcher-Watson 2010). With technological advances in detection tools, so came a new wave of studies addressing biological hypotheses for attention deficits. Throughout the past two decades, researchers hypothesized that inattentive behavior may be due to neural abnormalities in areas such as the parietal lobe and the frontal lobe (Courchesne et al. 1993, 1994; Ornitz 1988; Pascualvaca et al. 1998).

Current Knowledge

Developmental studies on attention reveal that attention evolves over the course of childhood and different patterns of attention behaviors are observed over time. The duration of time infants spend looking at objects or people, which reflects

differences in underlying attention processes (Kannass and Oakes 2008), increases from birth through 8 to 10 weeks, then decreases between 3 and 5 or 6 months, and remains stable or slightly increases thereafter (Colombo 2001, 2002). The initial increase of look duration may be due to steady increases in arousal and alertness, whereas the decrease of look duration may be indicative of improvements in information processing. The plateau reached near the first year is likely indicative of endogenous factors or top-down processes manifesting (Corbetta and Shulman 2002; Colombo 2001, 2002).

Children with autism appear to show different patterns of attention development than their typical peers. For example, the top-down processing that develops around the first year appears to pose difficulty for children with autism as compared to typically developing children (Ames and Fletcher-Watson 2010; Ames and Jarrold 2007; Leekam et al. 2000). Goldstein et al. (2001) also found that individuals with autism were different from their typical counterparts in their abilities to focus and shift attention, but were not different in their abilities to sustain and encode attention (Goldstein et al.). Another study found that children with autism had more circumscribed, preservative, and detail-oriented attention (Sasson 2008).

The results of studies involving eye tracking and visual attention in the context of social stimuli have also found differences among individuals with autism. One study indicated that when shown images of objects and people, individuals with autism generally attended to the nonsocial aspects of the picture, that is, objects rather than faces. Further, the investigation found that when individuals with autism did attend to social images, such as a human face, they looked at noncritical social elements, such as the nose rather than the eyes (Klin et al. 2002). Another study found that children with autism have difficulties processing both social and nonsocial information (Leekam et al. 2000). Collectively, the literature suggests that individuals with autism lack attention to social stimuli which undoubtedly affects social and emotional learning.

Future Directions

Attention abilities, from infancy throughout childhood, can have several effects on social relationships, language development, and cognitive development. Future work on attention in autism should aim to examine these processes in natural settings to more appropriately capture variables that facilitate and inhibit successful attention for this population within a variety of contexts, such as their social relationships and academic settings. Moreover, there is a need for greater longitudinal work in this area in order to understand how attentional processes develop over time and the extent to which these processes impact social and cognitive outcomes for individuals with ASDs (Ames and Fletcher-Watson 2010). Finally, attention has the potential to be an invaluable early detection tool for autism diagnoses. Children with autism face early and pervasive abnormalities in attention abilities (Allen and Courchesne 2001; Elsabbagh et al. 2009). The developmental course of attention in typical development has been outlined by previous investigations; future research could use such knowledge to examine attention in children at risk for autism early in infancy. Earlier screening and detection to earlier intervention which has been shown to yield improved outcomes for children with autism and other developmental delays.

ADD; ADHD; Attention deficit disorder; Hyperkinetic disorders; Minimal brain damage; Minimal brain dysfunction; Syndrome of deficits in attention, motor control, and perception (DAMP)

Short Description or Definition

Attention deficit/hyperactivity disorder (ADHD) is one of the most common psychiatric disorders in children and adolescents. It is characterized by inattention, impulsivity, and hyperactivity. Its rate decreases with the increase of age. ADHD usually starts in childhood and continues through adolescence into adulthood. The burden and psychosocial functioning impairment of ADHD is farther than its inattention, impulsivity, and hyperactivity symptoms. There are many controversies and scientific debates about ADHD (Biederman and Faraone 2005; Furman 2008).

Categorization

According to DSM-IV, there are three subtypes of ADHD called “predominantly inattentive,” “predominantly hyperactive-impulsive,” and “combined.” ICD-10 lacks this categorization.

Epidemiology

The prevalence of ADHD in children is estimated to be about 8–12% (Biederman and Faraone 2005). The rate of ADHD in boys is three times more than girls, and this ratio in the clinical sample is six to nine times (Ghanizadeh et al. 2008).

Natural History, Prognostic Factors, and Outcomes

From about two centuries ago, children with symptoms of inattention, impulsivity, and hyperactivity have been described (Crichton 2008; Lange et al. 2010). Heinrich Hoffmann described some symptoms of ADHD in the story of Fidgety Phil (Hoffmann (1948) cited by Lange et al. (2010)). Moral control defect was introduced by Sir George Frederic Still ((Still 1902) cited in Lange et al. (2010)). He reports that these children cannot internalize rules and limits. Then, the term of “postencephalitic behavior disorder” was introduced after the worldwide influenza epidemic (Rothenberger and Neumärker 2005) cited in Lange et al. (2010). The terms of “minimal brain damage” and “minimal brain dysfunction” were described (Hoffmann 1948). The name was changed to “hyperkinetic reaction of childhood” in the second edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-II) (American Psychiatric Association (APA) (1967). *Diagnostic and statistical manual for mental disorders*). Overactivity, restlessness, distractibility, and short attention span were the characteristics of this disorder (APA (1967). *Diagnostic and statistical manual for mental disorders*). In the third edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-III), the disorder was called “attention

deficit disorder (ADD): with and without hyperactivity.” In this edition, the focus was on inattentiveness rather than hyperactivity (APA (1980). *Diagnostic and statistical manual (DSM-III)*). In addition, it was stressed that hyperactivity was no more a necessary criterion for diagnosis of this disorder. From 1987, revision of the third edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-III-R), this disorder was renamed “attention deficit/hyperactivity disorder” (ADHD) (APA (1987). *Diagnostic and statistical manual (DSM-III, revised)*). In the DSM-III-R, the subtype of “ADD without hyperactivity” was replaced with the category of “undifferentiated ADD” (Lange et al. 2010). From the fourth edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV) (APA (1994). *Diagnostic and statistical manual (DSM-IV)*), the three subtypes of ADHD including “predominantly inattentive type,” “predominantly hyperactive-impulsive type,” and “combined type with symptoms of both dimensions” were presented (Lahey et al. 1994). There was no change regarding ADHD in the text revision of the fourth edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV-TR) (APA (2000). *Diagnostic and statistical manual (DSM-IV, Text Rev.)*). It is expected that DSM-V will be published in 2012.

Multiple comorbid disorders and parent-reported ADHD severity are associated with the poorer psychosocial quality of life (Klassen et al. 2004). The type of comorbidity is also associated with the quality of life. Lower quality of life is associated with the comorbidity of oppositional defiant disorder, conduct disorder, and learning disorder (Klassen et al. 2004). There is a positive short-term effect of medication on quality of life in children, adolescents, and adults with ADHD (Coghill 2010). Comorbidity of ODD with ADHD is associated with more severe ADHD symptoms, peer problems, and family problems (Ghanizadeh and Jafari 2010).

Children and adolescents with ADHD have poorer social and communication skills leading to more peer relationship problems. More than two-thirds of them have no close friends (Wehmeier et al. 2010). So, they are more

frequently rejected by others. This makes them more prone to join to deviant peer groups, injuries, occupational problems, educational problems, cigarettes, and substance use disorders (Biederman and Faraone 2005).

The symptoms of ADHD continue from childhood into adult. However, most of them will not meet the full diagnostic criteria in adult but they will meet the diagnosis of ADHD in partial remission (Fischer et al. 2002).

Clinical Expression and Pathophysiology

While there are many controversies about ADHD, the improvement of some symptoms after pharmacotherapy supports that there are neurobiological causes for the heterogeneous nature of ADHD. There is a large gap in our knowledge and current literature regarding ADHD. However, it is clear that there is not any one specific brain area or genetic or neurochemical factor as the etiology of ADHD.

The etiology of ADHD is complex (Steinhausen 2009). The heritability of ADHD is reported in twin and adoption studies. However, more molecular genetic studies are necessary to indicate the complex genetics and the interaction of gene by environment in ADHD (Biederman and Faraone 2005; Nigg et al. 2010).

There is not enough evidence supporting that ADHD is caused by foods or food additives (Biederman and Faraone 2005), while lead is reported to be associated with ADHD (Ghanizadeh 2011). Exposure to toxins such as mercury, lead, manganese, and polychlorinated biphenyls (PCBs) and pregnancy and delivery complications (such as eclampsia, maternal age, prenatal alcohol exposure, maternal smoking, fetal postmaturity, duration of labor, fetal distress, low birth weight, and hemorrhage) are other risk factors associated with ADHD (Banerjee et al. 2007). Meanwhile, TV viewing is not a risk factor for ADHD (Banerjee et al. 2007).

From the psychosocial factors, low family cohesion, exposure to parental psychopathology especially maternal psychopathology, low maternal education, low social class, and single

parenthood are important risk factors for ADHD (Biederman and Faraone 2005).

Brain structural studies do not report consistent findings for ADHD. However, most of imaging studies delineated overall decrease in total brain size, the caudate nucleus, prefrontal cortex white matter, corpus callosum and the cerebellar vermis (Tripp and Wickens 2009). Some of these areas have a high density of dopamine receptors.

Neuropsychological studies show the impairment of vigilance attention, executive function, working memory response, and motivation in some children with ADHD (Tripp and Wickens 2009). Brain maturation is delayed in ADHD (Curatolo et al. 2009).

Finally, children with ADHD may have difficulties in social exchanges such as sharing and cooperation with peers. They are self-centered, impulsive, and commanding (Wehmeier et al. 2010).

Evaluation and Differential Diagnosis

In many countries, ADHD diagnoses are generally made using Diagnostic and Statistical Manual, Fourth Edition, Text Revision (APA (2000). *Diagnostic and statistical manual (DSM-IV, Text Rev.)*). According to 4th Edition, Text Revision (DSM-IV-TR) criteria, there are two groups of symptoms including (a) attention deficit, (b) hyperactivity, or impulsivity. Six or more items from at least one of the groups are required for ADHD diagnosis. In addition, functional impairments in at least two different settings such as at home, school, and nursery are required.

In other countries, especially in Europe, International Classification of Diseases-10 (ICD-10) is used (World Health Organization (WHO) 1992). Hyperkinetic disorder is the ICD-10 equivalent of ADHD diagnosis (WHO 1992). In ICD-10, several items from attention deficit, hyperactivity, and impulsivity are required to reach diagnosis. Therefore, it is expected that the rate of ADHD in countries using DSM-IV-TR criteria would be reported higher than that of those countries using ICD-10 criteria.

ADHD diagnosis is subjective using the diagnostic systems criteria. There is not any objective

diagnostic test or any biomedical laboratory test for it. However, the ADHD diagnosis is reliable when well-trained raters assess and agree the presence of its symptoms (Biederman and Faraone 2005).

There is a weak correlation between different informants such as parents and teachers for the rating of ADHD symptoms. In other words, they usually do not agree on their assessment of symptoms in children with ADHD. The evaluation of children in different situations can be an explanation for this disagreement. Teachers evaluate children in school while the children are taking medication. Sometime, parents may report some symptoms that the symptoms are not reported by teachers.

In clinical samples, ADHD is usually comorbid with other psychiatric disorders. The rate of at least one comorbid psychiatric disorder in children with ADHD is more than 80% (Ghanizadeh et al. 2008). Other disruptive behavior disorders (oppositional defiant disorder (ODD) or conduct disorder (CD)) and anxiety disorders are the most common comorbid disorders in children with ADHD. The rate for ODD and CD is about 59.3% and 13.6% (Ghanizadeh et al. 2008). Some of the other comorbid disorders are mood disorders, tic disorder, enuresis, and encopresis.

It is interesting that the parent of children with ADHD usually suffer from psychiatric disorders. The lifetime prevalence of ADHD in fathers and mothers of children with ADHD are 45.8% and 17.7%, respectively. Major depressive disorder is very frequent in the parents. The rate in father and mothers are 48.1% and 43.0%, respectively (Ghanizadeh et al. 2008).

Co-occurrence of ADHD and Autism

ADHD DSM-IV-derived items do not overlap with autism spectrum disorder (Ghanizadeh 2010), and the comorbidity of ADHD and autism is precluded in the DSM-IV-TR. Therefore, the symptoms of inattentiveness, hyperactivity, or impulsivity in individuals with autism originate from autism, not ADHD. Meanwhile, there are many individuals who meet diagnostic criteria

for both ADHD and autism. In addition, many patients with Asperger's syndrome are screened with concerns about ADHD (Murray 2010). The children with autism may severely attend to their interest and do not attend to other factors in their environment. It can be interpreted as inattentiveness. Also, sometimes, their stereotypic motor behavior can be interpreted as hyperactivity (Murray 2010). However, there are many published studies reported the co-occurrence of ADHD and autism. About 40–78% of individuals with autism meet diagnostic criteria for DSM-IV ADHD (Murray 2010). Eighty-seven percent of children with autism spectrum disorder have at least one of the three components of ADHD (Ames and White 2011). The rate of autistic traits in children with ADHD is from one-third to one-fifth (Grzadzinski et al. 2011).

In addition, the subtype of ADHD is associated with the severity of difficulties in autism. For example, language and social problems are more common in those with both autism and ADHD-inattentive subtype. Moreover, less symptoms of autism are reported in those with ADHD-hyperactivity subtype. While internalizing behavior problems are usually seen in autism, externalizing behavior problems are more common in those with ADHD. A combination of externalizing and internalizing behavior problems are reported in those with both ADHD and autism (Murray 2010). Clinical profiles and outcomes of children with both ADHD and autism are different with that of those children with autism alone. They have severe social problems and poorer outcomes. Furthermore, executive function is more impaired in the individuals with both ADHD and autism than those with ADHD or autism alone. Motor coordination abnormalities are different between ADHD and autism. While motor response inhibition is more common in ADHD, motor planning impairment is more common in autism (Murray 2010). About two-thirds of children with the syndrome of deficits in attention, motor control, and perception (DAMP) meet diagnostic criteria for autism spectrum disorders. Comorbidity with developmental coordination problems is more likely to co-occur with autism symptoms than those with ADHD alone. Autism,

ADHD, and dyslexia overlap genetically (Smalley et al. 2005).

ADHD can be dissociated from autism spectrum disorders regarding executive dysfunction and response inhibition. Those with autism spectrum disorders are slow and accurate, while those with ADHD are impulsive (Johnston et al. 2011).

It is expected that the comorbidity of ADHD and autism spectrum disorders will be allowed in DSM-V. Then, autism will not be an exclusive criterion for ADHD diagnosis.

Treatment

The educating and counseling of parents (Ghanizadeh 2007), teachers (Ghanizadeh et al. 2006), and general physicians (Ghanizadeh and Zarei 2010) about ADHD is highly necessary and recommended. Many of parents, teachers, and medical service providers have not enough and updated knowledge towards ADHD symptoms and its management. Behavioral parent training is encouraged (van den Hoofdakker et al. 2007).

Drug therapy with stimulant drugs (Cornforth et al. 2010) and atomoxetine (Vaughan et al. 2009) is better than no drug therapy. However, there is not enough evidence indicating any difference between these medications regarding their efficacy or side effects (King et al. 2006).

The precise mechanism of stimulants in ADHD is not known. Noradrenaline and dopamine neurotransmitter systems are involved in ADHD. Methylphenidate and dextroamphetamine are stimulant medications which are effective in the management of ADHD. Atomoxetine is a nonstimulant catecholaminergic medication. They improve ADHD symptoms through increasing activation in cortical and subcortical regions involved in attention and executive functions (Curatolo et al. 2009). Meanwhile, there is a concern about the possible association of atomoxetine and increased suicidal behavior (Garnock-Jones and Keating 2009).

There are concerns about the higher rate of side effects of stimulants in individuals with both autism and ADHD than those with ADHD alone. In addition, methylphenidate efficacy in

autism is less than ADHD (Stigler et al. 2004). While the response rate is limited up to 25%, the rate of side effects reaches to 60% (Stigler et al. 2004). Dexamphetamine may worsen the symptoms (Handen et al. 2000).

Clonidine and guanfacine are α -2 agonists with promising efficacy on hyperactivity, impulsivity, irritability, explosive behaviors, stereotypies, and social interaction (Scahill et al. 2006).

Atomoxetine selectively inhibits the presynaptic norepinephrine transporter. There are contradictory reports about the efficacy of atomoxetine on ADHD symptoms in autism. While an open-label study supported its efficacy (Posey et al. 2006), others did not report a significant effect (Charnsil 2011).

Donepezil as a anticholinesterase inhibitor may decrease some symptoms of ADHD in children with autism (Yoo et al. 2007). Further controlled trials are required to detect the significant gains of these medications on autism.

There are open-label studies promising the efficacy of atypical antipsychotics, such as risperidone, quetiapine, and aripiprazole, on hyperactivity symptom in autism (Murray 2010).

Definition

Attention has been conceptualized as a multi-component system comprised of three isolable but interacting networks: alerting, orienting, and executive control (Posner and Petersen 1990). Alerting refers to the achievement and maintenance of a state of readiness to respond, orienting refers to the selection of an input pathway for further processing, and executive control refers to resolution of conflict between competing inputs and responses. The Attention Network Test (ANT), first described by Fan et al. (2002), was developed as a computerized tool for assessing the efficacy of each network.

In the ANT, participants are asked to fixate on a central cross responding to target arrows, which appear either above or below fixation. Targets are sometimes preceded by asterisks appearing at the center of the screen (center cue), above and below fixation simultaneously (double cue), or at the location of a subsequent target (spatial cue). In other words, cues may predict the onset (alerting cues) and/or location (orienting cues) of the target arrow. Finally, target arrows are flanked by arrows pointing in the same direction, arrows pointing in the opposite direction, or neutral bars. Network scores are typically calculated as differences in mean reaction time (RT) in opposing conditions. The orienting effect is the RT difference between center cue and spatial cue conditions, the alerting

effect is the RT difference between no-cue and double-cue conditions, and the executive control effect is the RT difference between congruent and flanker conditions.

Historical Background

Since the ANT was first introduced by Fan et al. (2002), substantial evidence has emerged supporting the biological validity of the three-network model. Unique neural patterns associated with each network have been identified using both electroencephalography (Fan et al. 2007) and functional magnetic resonance imaging (Fan et al. 2005). Furthermore, genetic studies suggest that there are heritable factors for executive control, as measured by the ANT (Fan et al. 2001).

Although the three attention networks are biologically and functionally distinct, and network scores are reliable across sessions (Ishigami and Klein 2010), frequently reported interaction effects between cue and flanker type suggest that these networks are not entirely independent (Fan et al. 2002; Ishigami and Klein 2010; Rueda et al. 2004). True independence is theoretically unlikely, assuming there is constant communication among functionally distinct brain regions and networks. Indeed, variations of the ANT have provided compelling evidence that the processes of orienting, alerting, and executive control do, in fact, modulate one another (e.g., Callejas et al. 2005; Fan et al. 2009; Fuentes and Campoy 2008).

Variants of the ANT have been developed to suit a range of purposes. For example, the child-ANT (ANT-C) features colorful, fish-shaped stimuli, which are meant to be more engaging for younger participants (Rueda et al. 2004). A lateralized version of the ANT (Greene et al. 2008) has been used to effectively isolate attentional processes in the left and right hemispheres. To better detect network differences, a revised version of the original ANT (ANT-R; Fan et al. 2009) modified a number of parameters, such as visual angle, cue-to-target interval, target duration, and target placement. The ANT-R also included orienting cues presented at locations

other than that of the target, known as “invalid” cues. In another version known as the ANT-interaction (ANT-I; Callejas et al. 2004), 50% of all spatial cues are invalid (i.e., they are “uninformative”). This version of the task additionally introduced auditory alerting tones to facilitate exploring the interaction between alerting and orienting networks. Recently, the ANT has been adapted into a game-like format in an effort to improve engagement relative to previous versions of the test. In the AttentionTrip (Klein et al. 2017), the participant uses a wheel to steer a spaceship through a wormhole while “shooting” target stimuli as they appear on the screen. This version of the task has been used with high-functioning adults on the autism spectrum (Mash et al. 2018) and may also demonstrate utility in research settings with young or lower-functioning individuals.

Current Knowledge

To date, there is a relatively small but growing body of literature reporting attention network scores in individuals with ASD. These studies have inconsistently reported significant differences between ASD and typically developing (TD) groups in all three major networks. Furthermore, these experiments vary considerably with respect to method (i.e., version of the ANT used), outcome variables reported (accuracy, reaction time), sample size, and age of the sample. In several studies, the sample sizes are quite small (e.g., $N = 12$) and therefore have limited power to detect negative results. However, several general themes have emerged from the extant literature that may guide future research.

Orienting

Problems with attention orienting and disengagement have been well-documented in individuals with ASD across the life span (Sacrey et al. 2014). Reduced orienting efficiency has been corroborated by several studies using versions of the ANT. In a sample of children and adolescents with and without ASD (ages 8–19), Keehn et al. (2010) found smaller orienting network scores on

the original ANT in the ASD group, likely reflecting reduced benefit of an orienting cue compared to the TD group. Less efficient orienting was similarly reported by Mutreja et al. (2016) in younger children with ASD (5–11 years) using the ANT-C. In a very small sample of older adolescents (six ASD and six TD, ages 16–17), Hames et al. (2016) did not find any significant group differences on the ANT-C with respect to orienting reaction time. However, they reported that the ASD group was more error-prone on orienting trials and that they tended to over-recruit brain regions typically associated with executive control during the orienting task. Although the above studies appear to implicate atypical orienting in younger individuals with ASD, other work has found relatively typical orienting on the ANT in both children (Ip et al. 2017; Samyn et al. 2017) and young adults (Fan et al. 2012; Mash et al. 2018) on the autism spectrum. Considering the critical role of attention orienting in early social development (Keehn et al. 2013), this is an important area of clarification for future research.

Alerting

Alerting network scores may reflect changes in both tonic and phasic alertness. Tonic alertness refers to intrinsic arousal, whereas phasic alertness is associated with rapid changes induced by a stimulus. Atypically large network scores may suggest reduced tonic alertness, resulting in slower reaction times in the absence of an alerting cue. Very small network scores, on the other hand, may be interpreted as reduced phasic alertness, resulting in only marginal improvements in reaction time in the presence of an alerting cue. In a study comparing typically developing children to those with ASD and attention-deficit/hyperactivity disorder (ADHD), alerting network scores on the ANT-I were significantly larger in the ADHD group, but were comparable in the ASD and TD groups (Samyn et al. 2017). A study using the original ANT reported no significant group differences in alerting between ASD and TD children and adolescents, but alerting network score size was associated with symptom severity in the ASD group. In contrast,

Mash et al. (2018) reported reduced alerting network scores in young adults using the original ANT, but not the AttentionTrip. In another sample of young adults tested on the ANT-R, Fan et al. (2012) reported that the ASD group made more errors in the absence of a cue, suggesting potentially poorer tonic alertness. Furthermore, using fMRI, they found that alerting errors were associated with reduced brain activity in the medial frontal gyri and caudate. As with orienting network scores, some research reported no significant group differences in alerting networks in ASD (Ip et al. 2017; Mutreja et al. 2016; Ridderinkhof et al. 2018; Samyn et al. 2017).

Executive Control

In general, studies of both children and adults measuring reaction time differences between congruent and incongruent flanker conditions on various versions of the ANT have found similar executive control networks in typical development and ASD (Fan et al. 2012; Hames et al. 2016; Ip et al. 2017; Keehn et al. 2010; Mash et al. 2018; Mutreja et al. 2016; Ridderinkhof et al. 2018; Samyn et al. 2017). One of these studies described an inverse relationship between IQ and the size of the executive control network in children and adolescents with ASD (Keehn et al. 2010), suggesting that inefficient executive processes (i.e., slower reaction time on incongruent trials) may be directly related to general cognitive ability. Supporting this possibility, they did not find any relationship between executive control and ASD symptoms. This study additionally reported that the alerting and executive control networks demonstrated unusually high interdependence in ASD individuals. The authors speculated that this might reflect compensatory executive strategies to control alertness in individuals with poorer intrinsic regulation of arousal. Although reaction times tend to be similar in ASD and TD individuals, there is some evidence that ASD individuals show significantly reduced accuracy on incongruent trials relative to congruent trials, resulting in larger accuracy difference scores. Mutreja et al. (2016) reported this effect in children (ages 5–11) using the ANT-C; a similar finding that did not reach statistical significance

was reported in a larger sample of slightly older group of individuals aged 8–23 (Ridderinkhof et al. 2018). Using the ANT-R, Fan et al. (2012) demonstrated poorer executive control accuracy in adults with ASD; further, they found that less accurate performance on the flanker component of the task was associated with reduced activation in the anterior cingulate cortex and more severe language and communication symptoms in the ASD group. Therefore, although individuals with ASD do not appear to respond more slowly to incongruent flankers, error analysis suggests that they may trade speed for accuracy on this task. Furthermore, it appears that accuracy, but not reaction time, may relate to behavioral and brain markers of ASD.

Future Directions

Studies examining attention using ANT-like tasks have provided some insight into attention network function in individuals with ASD. For example, participants on the autism spectrum generally tend to demonstrate reduced orienting efficiency, as well as poorer task accuracy when resolving conflict. However, even these relatively well-established findings have not been consistent across studies. Although ANT tasks are increasingly used and reported in ASD research, this body of literature remains fairly small and heterogeneous. There is great deal of variability with respect to participant age, sample size, ANT version, and outcome measures reported, which complicates direct comparison of findings. However, further study with adequate sample sizes may help to clarify the details of some of the emerging themes in this field.

A main disadvantage of the ANT is its length and repetitive nature. This may pose a challenge for populations that may have difficulty with sustained attention. Often, such individuals are of greatest interest to researchers studying attention. However, insufficient or variable effort throughout the entire task may preclude accurate interpretation of the resulting data. A recently developed, game-like version of the ANT (the AttentionTrip; Klein et al. 2017) may help to mitigate problems with engagement in

younger or cognitively impaired groups. The AttentionTrip has been used successfully in high-functioning adults on the autism spectrum (Mash et al. 2018), but future work may establish whether it can improve engagement in children or lower-functioning participants with ASD.

Attention Process Training (APT) Program

Corey Ray-Subramanian
Waisman Center, University of Wisconsin-
Madison, Madison, WI, USA

Definition

The Attention Process Training (APT and APT-II) program is a cognitive rehabilitation intervention that targets focused, sustained, selective, alternating, and divided attention (Sohlberg and Mateer 1987; Sohlberg et al. 2001). APT developers define focused attention as the ability to respond to specific stimuli. Sustained attention refers to the ability to consistently respond during a continuous or repetitive activity. Selective attention is the ability to activate and inhibit responses based on discrimination of stimuli. Alternating attention refers to aptitude for mental flexibility, and divided attention has been defined as the ability to engage in multiple tasks simultaneously.

In general, process training involves implementing a structured treatment program to improve attention skills in a variety of areas (Sohlberg et al. 2001). The APT materials consist of tasks that are hierarchically organized to target sustained, selective, alternating, and divided attention (Sohlberg et al. 2001). The hierarchical

structure is intended to allow for basic skills to be constantly utilized while developing and practicing more complex skills (Palmese and Raskin 2000). Auditory attention tapes and visual activities are used for some of the tasks. APT also includes exercises to facilitate generalization of skills to daily life (Palmese & Raskin). The APT approach has been referred to as process-specific cognitive rehabilitation because it is intended to improve particular types of attention skills and does not lead to improvements in overall cognitive functioning (Sohlberg and Mateer 1987).

Historical Background

APT was developed by Sohlberg and Mateer (1987) based on experimental attention literature, clinical observation, and patients' subjective reports of symptoms. It frames attention as a multidimensional cognitive capacity (Sohlberg & Mateer). The APT-II is an extension of the original APT and is designed to target more complex attention impairments (Murray et al. 2006).

Rationale or Underlying Theory

APT follows a process-specific approach to cognitive rehabilitation in that it is intended to improve functioning in distinct cognitive areas (Sohlberg and Mateer 1987). The rationale underlying APT is that learning specific skills may help improve some of the cognitive problems that result from acquired brain damage (Park et al. 1999). A process-specific approach can be contrasted with the functional adaptation and the general stimulation perspectives. The functional adaptation approach utilizes task analysis and changes in the environment to assist with the challenges associated with cognitive impairments. The general stimulation approach utilizes tasks that facilitate any type of cognitive processing. These prior approaches to cognitive rehabilitation have been criticized as leading to poor generalizability and lacking a theoretical orientation, respectively (Sohlberg and Mateer 1987; Sohlberg et al. 2001).

Goals and Objectives

The objectives of APT are to improve individuals' focused attention, sustained attention, selective attention, alternating attention, and divided attention skills following an acquired brain injury, although the program has also been used with other populations. Individualized treatment goals are created based on the needs of the client in each of these areas of attention.

Treatment Participants

Although APT was designed for use with individuals who have acquired brain injury and most published research on the APT has been based on this population, some researchers have examined the efficacy of APT for individuals with schizophrenia and aphasia. Little is known about the efficacy of the program with other populations. Some have suggested that APT could be beneficial for individuals with autism spectrum disorders (Ozonoff et al. 2005), although published efficacy research to date has not been conducted with this population.

Treatment Procedures

The APT program is comprised of a set of activities that have a common structure and that range in complexity and processing speed requirements (Sohlberg and Mateer 1987). Treatment goals are individualized based on the client's impairments in each of the attention areas targeted (i.e., sustained, selective, alternating, and divided). Each task is designed to offer practice in one or more levels of attention. The tasks are either client-paced or therapist-paced depending on the nature of the exercise (Park et al. 1999).

The APT-II includes general exercises, each requiring approximately 5 min to complete, for each of the specific areas of attention emphasized in the program (Palmese and Raskin 2000). Four types of activities are incorporated into APT:

visual cancelation, auditory cancelation, mental control, and daily life attentional activities (López-Luengo and Vázquez 2003). Within each exercise, there are tasks that increase in speed and difficulty. When the client completes the final activity for a particular sequence, he or she can advance to the next level. Each exercise is repeated until it is completed successfully according to specified criteria. Some researchers have noted that the linguistic demands of APT tasks need to be taken into account for treatment planning with patients who have language impairments (Murray et al. 2006).

In the area of sustained attention, examples of visual activities include cancelation tasks (e.g., crossing out all the *Ps* and *Cs* in a long series of letters) where the client is scored on completion time, omissions, and errors. Audio activities include tasks such as having the client press a button when he or she hears a target stimulus among a set of distracters (e.g., identifying items that are round from a list of words) and is scored for accuracy (Pero et al. 2006). For selective attention, tasks from sustained attention are included but with more irrelevant and distracting stimuli added (e.g., auditory stimuli recorded over a noisy background). Similar tasks are also incorporated into the alternating attention activities but with instructions to change the target stimuli every 15 seconds. The divided attention activities include completing the visual and auditory cancelation tasks simultaneously, as well as card sorting and Stroop tasks (Pero et al.). Solving math problems and identifying main ideas from paragraphs are also examples of APT tasks (Palmese and Raskin 2000).

The program does not specify a particular number of sessions but recommends that response time should be decreased by 35% before moving on to the next task and that the client achieve 85% accuracy on each task (Pero et al. 2006). Researchers examining the efficacy of the APT program have generally implemented the intervention for a range of 4–10 weeks at a frequency of one to nine sessions per week (e.g., Coelho 2005; Palmese and Raskin 2000; Sohlberg and Mateer 1987; Sohlberg et al. 2000).

Efficacy Information

There is some evidence that APT may lead to improvements in specific attentional skills but not in general cognitive functioning. Most of the efficacy research for APT has been based on single-case designs with small sample sizes (e.g., Coelho 2005; Murray et al. 2006; Palmese and Raskin 2000; Pero et al. 2006; Sohlberg and Mateer 1987), although a few studies have incorporated between-group designs with random assignment (e.g., López-Luengo and Vázquez 2003; Sohlberg et al. 2000).

In general, researchers have found some support for improvement on sustained, selective, and divided attention tasks, as well as reading comprehension, in certain situations (Boman et al. 2004; Coelho 2005; Kurtz et al. 2001; Murray et al. 2006; Palmese and Raskin 2000; Pero et al. 2006; Sohlberg et al. 2000; Sohlberg and Mateer 1987). However, studies have not consistently found evidence of improvement in attention skills resulting from APT (e.g., López-Luengo and Vázquez 2003; Silverstein et al. 2005).

For example, individuals with brain injury who have completed the APT program have shown improvement on the paced auditory serial addition task (PASAT; Gronwall 1977), a measure of sustained attention and information processing speed (Park et al. 1999). However, control subjects who did not receive APT also showed improvement on this task over time (Park et al.). Compared to individuals receiving brain injury education, those who received APT in another study made greater gains on the PASAT (Sohlberg et al. 2000).

Another task on which individuals with brain injury who have completed APT have shown improvement is the consonant trigrams activity (Park et al. 1999), which involves recalling three consonants heard after counting backward by threes. It is intended to measure memory under conditions of distraction.

Researchers have also found some support for improved performance on the Trails-B task for individuals with brain injury who completed APT compared to a group who completed a brain injury education program (Sohlberg et al. 2000). This task requires participants to draw lines connecting a

sequence of ascending numbers and letters (e.g., 1-A-2-B-3-C-4-D...).

In addition to attention tasks, some studies have examined performance on executive function tasks following the APT program in samples with brain injury and schizophrenia (López-Luengo and Vázquez 2003; Sohlberg et al. 2000). One such task on which participants have shown improvement after completing APT is on variations of the Stroop task (Stroop 1935; Mohlman 2008; Sohlberg et al. 2000).

Outcome Measurement

A variety of outcome measures including attention tasks, questionnaires, and participant interviews have been used in APT efficacy research. However the most commonly used outcome measures appear to be the paced auditory serial addition task (PASAT; Gronwall 1977), consonant trigrams (Peterson and Peterson 1959), Trails B, and variations of the Stroop task (Stroop 1935).

Paced Auditory Serial Addition Task

The PASAT measures rate of information processing and was designed to assess the rate and degree of progress for clients recovering from concussion (Gronwall 1977). It is comprised of a randomized presentation of an auditory digit sequence, and the participant is expected to add each new digit to the preceding one (Sohlberg et al. 2000). Subsequent trials are presented at increasingly faster rates. Scores can be calculated as the correct number of responses at each trial pace or average time per correct response (Gronwall 1977). The PASAT is considered to require two types of attention: sustained attention and the ability to identify and correct errors during the activity (Park et al. 1999). Some have questioned whether improvement on this task following APT is due to the intervention or is an effect of repeated testing (Pero et al. 2006).

Consonant Trigrams/Brown-Peterson Task

This task measures memory skills under conditions of distraction (Park et al. 1999). Individuals participating in this task hear three consonants followed by a number. They are then asked to

count backward by threes for a predetermined number of seconds (e.g., 3, 9, 18). After the set time has elapsed, the participant is expected to recall the three consonants heard at the beginning of the trial. Delays of varying lengths between the end of the counting backward and the instruction to recall the consonants are also incorporated into the assessment (Park et al.).

Trails B

Trails B was originally part of the Army Individual Test Battery and is a task that measures visual scanning, mental flexibility, planning abilities, and working memory (Corrigan and Hinkeldey 1987; Sohlberg et al. 2000). Participants are asked to draw lines connecting consecutively numbered and lettered circles and alternate between the two (e.g., in the order 1-A-2-B-3-C-4-D...). Trails B can be scored as number of seconds required to complete the task (Corrigan and Hinkeldey 1987).

The Stroop Task

The Stroop task measures the interference effects of conflicting stimuli (Stroop 1935). Participants are shown a list of color words and asked to name the colors in which the words are printed (e.g., red, yellow) and ignore the words themselves (e.g., naming “yellow” for the word “red” printed in yellow ink). The task can also be completed by having participants read the list of color words while ignoring the ink color in which they are printed. Many variations of this original task have been developed that utilize different types of conflicting stimuli (MacLeod 1991).

Qualifications of Treatment Providers

Psychologists, speech-language pathologists, occupational therapists, special education staff, and related professionals with appropriate training in cognitive rehabilitation would generally be considered qualified to implement APT.

Attentional Disengagement

Brandon Keehn

Department of Speech, Language, and Hearing Sciences, Department of Psychological Sciences, Purdue University, West Lafayette, IN, USA

Definition

The first of the three subfunctions necessary for visual-spatial orienting (disengage, shift, and engage); the removal of attention from and/or ocular engagement with a stimulus that enables a shift of attention from one location to another.

Historical Background

Attention and autism spectrum disorder. Although autism spectrum disorder (ASD) is

diagnosed on the basis of impairments in social interaction and communication as well as the presence of repetitive and stereotyped interests and behaviors (APA 2013), differences in attention have been noted as secondary or associated features since the disorder was first described (Asperger 1944; Kanner 1943). For example, in his original account, Asperger (1944) observed that:

We regularly find a disturbance of active attention in autistic children. Here we are not [...] talking about the common-or-garden problems of concentration. These are problems that we find in many [children with other developmental disabilities] who are constantly distracted from work by external stimuli [...]. Autistic children on the other hand are, from the start, not interested in directing their attention to outside stimuli [...]. They follow their own ideas, which are mostly far removed from ordinary concerns, and do not like to be distracted from their thoughts.

Likewise, for one of his original 11 cases, Kanner (1943) remarked that, “to get his attention almost requires one to break down a mental barrier between his inner consciousness and the outside world” (p. 218). However, it was not until the 1960s and 1970s that research focused on the attentional differences in individuals with ASD began in earnest with the work of Hutt et al. (1964), Hermelin and O’Connor (1964), as well as Lovaas et al. (1971). Later, pioneering research led by Michael Posner (1980) investigating *visual-spatial orienting* in neurotypical individuals as well as those with cortical and subcortical lesions (Posner et al. 1982) illuminated this basic cognitive process and its associated brain network. Based on this work, Posner et al. (1984) later outlined the subcomponents of visual-spatial orienting: disengaging, shifting, and reengaging attention. Attentional disengagement thus reflects the initial step of the orienting process and is a prerequisite for shifting and then engaging a new object, person, or location within one’s environment. Subsequent research using Posner’s cuing paradigm in ASD provided the first evidence of impaired nonsocial visual-spatial orienting and in particular showed deficits in disengaging attention (Casey et al. 1993; Townsend et al. 1996; Wainwright-Sharp and Bryson 1993).

Current Knowledge

How do we measure disengagement? In addition to the Posner cuing paradigm, attentional disengagement in ASD has primarily been measured using gap-overlap tasks, which examine differences in the latency of eye movements to peripheral targets appearing with, and without, a central stimulus (Saslow 1967). The time required to execute saccadic eye movements (also referred to as saccadic reaction time; SRT) is reduced when a fixated central stimulus is removed prior to (i.e., gap condition) or simultaneously with (i.e., baseline or step condition) the onset of a peripheral target compared to when the central stimulus remains on screen when the peripheral target appears (i.e., overlap condition). Attentional disengagement, as measured by the gap effect (i.e., overlap SRT – gap SRT), is associated with both attentional and oculomotor components, and arises from two distinct sources: (1) a generalized alerting effect as a consequence of the fixation offset, which cues participants about the impending peripheral target and (2) the release of ocular inhibition due to (a) removal of the foveal stimulus and (b) top-down preparation of a saccade (e.g., Kingstone and Klein 1993). Disengagement abilities have been measured using modified gap-overlap paradigms across the lifespan from infants at risk for ASD (because they have an older sibling diagnosed with the disorder) to adults diagnosed with ASD (see Sacrey et al. 2014, for review).

Attentional disengagement in ASD. Results of studies employing gap-overlap paradigms in ASD are mixed with evidence of equivalent (e.g., Fischer et al. 2016; Schmitt et al. 2014; Zalla et al. 2018), slower (Elison et al. 2013; Elsabbagh et al. 2013; Kawakubo et al. 2007; Kleberg et al. 2017; Landry and Bryson 2004; Sabatos-DeVito et al. 2016), and faster (van der Geest et al. 2001) disengagement. Evidence of impaired disengagement in ASD has received the most support from studies of high-risk infant siblings of children with ASD and has now been replicated by three separate research groups using unique cohorts of infants (Bryson et al. 2018; Elison et al. 2013; Elsabbagh et al. 2013). This

deficit in attentional disengagement emerges around the end of the first year of life and has been shown to persist in children (Kleberg et al. 2017; Landry and Bryson 2004; Sabatos-DeVito et al. 2016) and adults (Kawakubo et al. 2007). Further, while these studies examining attentional disengagement in ASD have almost exclusively used visual stimuli, Keehn et al. (2019) recently showed reduced disengagement efficiency in children with ASD in the auditory domain, suggesting that disengagement impairments in ASD are not specific to the visual modality. Interestingly, this impairment in attentional disengagement is essentially in accord with the early anecdotal accounts by Kanner (1943) and Asperger (1944). That is, difficulties disengaging attention may manifest themselves in becoming “stuck” and subsequently failing to “direct their attention to outside stimuli.”

However, as referenced above, not all investigations have reported impairments in attentional disengagement in ASD. Inconsistent findings may arise from a variety of sources including the heterogeneous nature of ASD, the ages investigated, and differences in task design. Regarding the latter point, Keehn et al. (2019) noted two methodological factors that may contribute to the presence or absence of disengagement differences in ASD: (1) the type of fixation stimulus (e.g., dynamic or static images) and (2) predictability in the sequence of stimuli. For example, disengagement impairments are more commonly reported in studies of infants and young children, which primarily employ dynamic stimuli to maintain engagement of these younger participants, whereas studies of older children, adolescents, and adults with ASD tend to use more basic stimuli (e.g., fixation cross, LEDs). Second, at least two key aspects of gap-overlap tasks can be varied to decrease/increase the predictability of the target onset: (1) whether the central stimulus has a fixed or a variable duration and (2) whether trial types are blocked or randomized. In both cases, studies with more predictable stimulus sequences – central stimulus present for fixed duration and blocked trial type (e.g., all overlap trials presented together) – commonly report no group differences in disengagement, whereas evidence of impaired

disengagement is more consistently found with unpredictable tasks. Furthermore, gap trials provide a predictable sequence of events: (1) fixation cross appears, (2) fixation cross is removed (fixed duration; e.g., 200 ms), and (3) peripheral target onset. Thus, disappearance of the central fixation in gap trials, regardless of study paradigm, always provides a fixed cue associated with the appearance of the target. Group differences in SRT are almost never present in the gap condition; rather, significantly larger gap effect scores in ASD (which are indicative of slower, less efficient disengagement) are the result of longer latencies to shift in overlap trials.

In sum, deficits in attentional disengagement appear to be present within the first year of life and persist across the lifespan in individuals with ASD. Although evidence of equivalent performance on measures of disengagement exists, these findings may result, in part, from specific methodological variations in task design. Together, these results suggest that ASD is associated with impairments in disengaging attention, which are likely exacerbated when engagement with the fixated stimulus is high and/or target onset is unpredictable. Further, while these deficits in attentional disengagement may manifest as subtle differences in the latency of eye movements during well-controlled laboratory experiments, it is likely that these differences are amplified in real-world contexts, which are engaging and unpredictable.

Neural substrates of attentional disengagement. The network of brain regions responsible for orienting attention include the superior parietal lobes, intraparietal sulci, temporal-parietal junction (TPJ), and the frontal eye fields (FEF), as well as the thalamus and superior colliculus (SC) (Corbetta et al. 2008; Petersen and Posner 2012). In particular, the right TPJ may be a critical hub connecting both cortical (i.e., FEF) and subcortical (i.e., SC) brain regions (Bogadhi et al. 2019) and is thought to play a key role in disengaging and reorienting attention. Bryson et al. (1990) previously hypothesized that ASD could be characterized as a developmental spatial neglect syndrome (with acquired spatial neglect in adults generally associated with posterior right

hemisphere brain lesions). More recently, these authors have shown asymmetrical disengagement deficits in high-risk infants. That is, consistent with their prediction of neglect-like patterns of behavior, infants later diagnosed with ASD showed atypically slowed left-directed SRT when the fixation stimulus remained on screen (i.e., overlap trials). This theory and associated empirical results are consistent with electrophysiological (e.g., Orekhova et al. 2009) and neuroimaging findings (e.g., Keehn et al. 2016) of atypical right hemisphere activation in individuals with ASD. However, the particular neural mechanism(s) underlying disengagement deficits in ASD remains unknown.

Clinical significance. Early adaptive allocation of attention to one's environment requires efficient attentional disengagement and shifting. Failure to respond to a caregiver's name call or touch or the appearance of a novel object may result in fewer learning opportunities and affect the development of higher-level cognitive and social communication abilities. High-risk infants later diagnosed with ASD exhibit impairments in attentional disengagement compared both high- and low-risk infants that do not develop ASD. The presence of these early deficits in attentional disengagement has led some authors to hypothesize that they may be one of many factors that contribute to the emergence of the heterogeneous ASD phenotype (Keehn et al. 2013). Findings from prior research has demonstrated that disengagement efficiency in ASD is associated joint attention abilities (Schietecatte et al. 2011), recognition of spoken words (Venker 2017), and emotional distress (Bryson et al. 2018). For example, if infants and toddlers are unable to disengage and shift their attention during early dyadic interactions, then they may not follow a caregiver's point (i.e., respond to joint attention bid) or direct their caregiver's attention to a new item in their environment (i.e., to initiate joint attention). Thus, basic nonsocial attentional processes, such as attentional disengagement, may play a role in the development of core sociocommunicative impairments in ASD. These subsequent impairments (e.g., with joint attention) may have downstream consequences with word learning and language

development and thus may alter developmental trajectories across a variety of domains.

Future Directions

Identifying underlying mechanisms of impaired disengagement. Although strong evidence now exists for slower attentional disengagement in ASD, the mechanisms underlying these differences remain unclear. Elucidating the neurofunctional underpinnings associated with early disengagement impairments in ASD is a necessary next step to understand why this deficit emerges, how it may be used to accurately identify infants at risk, and how to more effectively target this skill in early intervention.

Leveraging attentional disengagement for early diagnosis and intervention. If disengagement impairments are present early (within first year of life) and play a critical role in the development of ASD, then (1) disengagement deficits may be used as an early biobehavioral marker to identify infants at risk for ASD and (2) the development of attention-targeted early interventions may augment early disengagement skills and improve outcomes in children with ASD. Eye-tracking biomarkers for ASD risk that focus on preference for social compared to nonsocial stimuli have shown excellent specificity but poor sensitivity (Pierce et al. 2016). Similar research examining the utility of nonsocial attentional disengagement metrics for classifying ASD risk has not yet been published. Such research – especially in community-based high-risk samples – will assist the field in identifying whether attentional disengagement may be used a biobehavioral marker for ASD risk. Further, research examining the role of atypical attentional disengagement on the development of ASD symptoms will advance our understanding regarding the utility of early attention-targeted interventions. For example, if early disengagement difficulties result in delayed or impaired joint attention in ASD, then targeting these early attention skills may facilitate the acquisition of this pivotal skill (Forssman and Wass 2018) and potentially result in improved outcomes for children with ASD.

Attributions (First Order/Second Order)

Francesca Happé

MRC Social, Genetic and Developmental Psychiatry Centre, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, UK

Synonyms

[Attribution of mental states](#)

Definition

Attribution is a concept in psychology referring to people's tendency to attribute traits and causes to help explain what they observe. First- and second-order attributions refer more specifically to the attribution of mental states to self or others to explain and predict observable behavior (see ► [“Theory of Mind”](#)). Attribution of mental states, such as beliefs and desires, has been widely studied in false belief paradigms (Frith and Frith 2010). First-order mental state attribution tasks require the participant to represent another person's thoughts about the world, e.g., Sally *thinks* the ball is in the basket. Second-order tasks require representation of one person's belief about another person's mental state, e.g., Sally *thinks* Ann *knows* the ball is in the box. An everyday life example of attribution of mental states would be when we understand whether someone is telling a joke or telling a lie: we attribute to the liar, but not to the joker, the intention to make us believe what he or she says. Several tests exist for assessing the ability to attribute mental states (e.g., Happé 1994; White et al. 2009).

A large body of research has demonstrated that most children and many adults with ASD find it difficult to make mental state attributions, especially attributing to another person a state of knowledge that is different from their own or from reality (Baron-Cohen et al. 2000). This may underlie a range of social and communicative

Attribution of Mental States

► [Attributions \(First Order/Second Order\)](#)

symptoms in ASD, such as overliteral language use/understanding, difficulty adapting conversation to listeners' interests/knowledge, and difficulty understanding deception. An interesting question in recent research (e.g., Williams and Happé 2009) is whether some people with ASD may have difficulty attributing mental states to *self*, with implications for self-awareness and the ability to reflect upon one's own thoughts and feelings.

Attribution of mental states has become a key task for use during functional neuroimaging investigations of brain differences in ASD. A range of different tasks suggest key regions including the medial prefrontal cortex are less activated in people with ASD compared to controls when attributing thoughts (in response to, e.g., animated shapes, story vignettes; Frith and Frith 2010).

Synonyms

[Novel antipsychotics](#); [Second-generation antipsychotics \(SGAs\)](#)

Indications

Aripiprazole (Abilify)

Schizophrenia in adults and pediatric patients (age 13–17 years); Acute manic or mixed episodes of bipolar I disorder in adults and pediatric patients (age 10–17 years), alone or as an adjunct to lithium or valproate; Major depressive disorder in adults (adjunctive treatment); Agitation associated with schizophrenia or manic or mixed episodes of bipolar I disorder (adults).

Clozapine (Clozaril)

Acute schizophrenia; Acute schizoaffective disorder; Treatment-refractory schizophrenia; Maintenance therapy in schizophrenia; Manic episodes of bipolar disorder; Depression with psychotic features.

Olanzapine (Zyprexa)

Schizophrenia in adults and pediatric patients (age 13–17 years); Acute manic or mixed episodes of bipolar I disorder in adults and pediatric patients (age 13–17 years), alone or as an adjunct to lithium or valproate; Acute agitation in schizophrenia and mania in bipolar I disorder; in combination with fluoxetine for depressive episodes associated with bipolar I disorder in adults; in combination with fluoxetine for treatment-resistant depression (adults).

Olanzapine and Fluoxetine Hydrochloride (Symbyax)

Acute depressive episodes of bipolar I disorder in adults; Treatment-resistant depression in adults.

Paliperidone (Invega)

Schizophrenia; Acute treatment of schizoaffective disorder, alone or as an adjunct to mood stabilizers and/or antidepressants.

Quetiapine (Seroquel)

Schizophrenia, including global symptoms, positive symptoms, negative symptoms, cognition, and aggression; Bipolar disorder (adults); Major depressive disorder in adults (adjunctive treatment).

Risperidone (Risperdal)

Schizophrenia in adults and pediatric patients (age 13–17 years); Acute manic or mixed episodes of bipolar I disorder in adults, alone or as an adjunct to lithium or valproate; Acute manic or mixed episodes of bipolar I disorder in pediatric patients (age 10–17 years); Irritability associated with autistic disorder in pediatric patients (age 5–16 years).

Ziprasidone Hydrochloride (Geodon) and Ziprasidone Mesylate (Geodon)

Schizophrenia in adults; Acute manic or mixed episodes of bipolar I disorder in adults, alone or as an adjunct to lithium or valproate; Acute agitation of schizophrenia in adults

Mechanisms of Action

When considering mechanisms of action of antipsychotics, it is important to note that the

pathophysiologies of psychiatric conditions treated by these drugs (i.e., schizophrenia, bipolar disorder, and autism) are unknown; therefore, the precise mechanisms of action of the atypical antipsychotics are unknown.

Aripiprazole

Aripiprazole is a dopamine type 2 (D_2) receptor partial agonist, not a full antagonist like the other atypical antipsychotics. This drug acts as a D_2 receptor antagonist when coadministered with a dopamine (DA) agonist but acts as a D_2 receptor agonist when administered without another DA agonist. Aripiprazole acts as an antagonist in overactive DA pathways and an agonist in underactive DA pathways. This drug's antagonist activity at serotonin type 2A ($5-HT_{2A}$) receptors may cause reductions in extrapyramidal symptoms (EPS) and improve the negative symptoms of schizophrenia, and its partial agonist activity at serotonin type 1A ($5-HT_{1A}$) may cause improvement in the negative and cognitive symptoms of schizophrenia, depression, and anxiety.

Clozapine

Clozapine exhibits low affinity for and quick dissociation from dopamine type 2 (D_2) receptors and high affinity for the serotonin type 2A ($5-HT_{2A}$) and serotonin type 1C ($5-HT_{1C}$) receptors, adrenergic receptors, cholinergic receptors, and dopamine type 4 (D_4) receptors, mainly in the extrastriatal cortex as compared to the striatal cortex. This drug also increases the release of dopamine (DA) in the prefrontal cortex. This effect of the drug may alleviate the negative symptoms and cognitive deficits of schizophrenia since these two aspects of the disorder may result from dopaminergic hypoactivity in the prefrontal cortex.

Olanzapine

Olanzapine has high relative serotonin type 2A ($5-HT_{2A}$) receptor blocking activity compared to that of dopaminergic (DA) receptors. This drug increases expression of *c-fos* in the caudate nucleus and increases serum glutamate levels. Also, olanzapine increases brain glutamate levels in patients who exhibit improvement in the negative symptoms of schizophrenia.

Paliperidone

Paliperidone is a dopamine type 2 (D_2), serotonin type 2A ($5-HT_{2A}$), α_1 - and α_2 -adrenergic, and histaminergic 1 (H_1) receptor antagonist. This drug is expected to have a mechanism very similar to that of risperidone since it is the major active metabolite of that drug, although patients have been reported to have responded positively to paliperidone after failing to respond to an adequate trial of risperidone.

Quetiapine

Quetiapine exhibits a high relative blockade of serotonin type 2A ($5-HT_{2A}$), serotonin type 2B ($5-HT_{2B}$), and serotonin type 2C ($5-HT_{2C}$) receptors compared to that of dopamine (DA) receptors. This drug exhibits a greater degree of binding in the extrastriatal cortex than in the striatal cortex. Quetiapine has partial agonist activity at $5-HT_{2A}$ which causes an increased DA level in the mesocortical DA pathway in individuals in which this pathway is hypoactive, thereby causing improvement in the negative and cognitive symptoms of schizophrenia. Also, this compound exhibits brief, high occupancy of dopamine type 2 (D_2) receptors for 2–3 h after dose administration in patients who exhibit improvement in psychosis, extrapyramidal symptoms (EPS), and prolactin. Imaging studies show that this drug has means of 74% $5-HT_{2A}$ receptor binding and 30% D_2 receptor binding for 450 mg/day dosing and means of 76% $5-HT_{2A}$ receptor binding and 41% D_2 receptor binding for 750 mg/day dosing.

Risperidone

Risperidone acts as an antagonist at the serotonin type 2A ($5-HT_{2A}$), dopamine type 2 (D_2), α_1 - and α_2 -adrenergic, and histaminergic 1 (H_1) receptors. Selective $5-HT_{2A}$ antagonists block amphetamine- and phencyclidine-induced locomotor activity and thereby may improve symptoms of psychosis. Also, the dizocilpine-induced disruption of prepulse inhibition of $5-HT_{2A}$ antagonists may improve sensory gating deficits in schizophrenia which may be caused by glutamatergic dysregulation. The α -adrenergic antagonist activity may cause an increase in dopamine (DA) levels in the medial prefrontal cortex which may

improve negative symptoms and cognition in schizophrenia. Dopaminergic hypoactivity in the prefrontal cortex is a potential cause of negative symptoms and cognitive deficits in schizophrenia. The α -adrenergic antagonist activity of this drug also may reduce the risk for the development of extrapyramidal symptoms (EPS) and improve cognition in individuals with frontal dementias. When taken with haloperidol, the selective serotonin type 2 ($5-HT_2$) antagonism reduces neuroleptic-induced parkinsonism and akathisia by increasing DA metabolism in the striatum and preventing an increase in D_2 receptor density which causes a decrease in the effects of D_2 receptor blockade and DA supersensitivity.

Ziprasidone

The antipsychotic effects of ziprasidone may be due to the affinity of this drug for dopamine type 2 (D_2) receptors in the striatum and its strong antagonism for serotonin type 2A ($5-HT_{2A}$) receptors. The $5-HT_{2A}$ receptor antagonism of this drug and its strong serotonin type 1A ($5-HT_{1A}$) receptor agonism may improve the negative and cognitive symptoms of schizophrenia by facilitating the release of dopamine (DA) in the prefrontal cortex.

Specific Compounds and Properties

The specific compounds currently marketed in the United States that act as atypical antipsychotics are aripiprazole, clozapine, olanzapine, paliperidone, risperidone, ziprasidone, and quetiapine. The unique chemical structure of each atypical antipsychotic accounts for its binding activity as detailed in the “Mechanisms of Action” section of this entry. The chemical structures of these compounds are pictured in Figs. 1, 2, 3, 4, 5, 6, and 7

Clinical Use (Including Side Effects)

Aripiprazole

Aripiprazole is used in autistic disorder to improve symptoms of aggression, irritability, and self-injurious behavior. Doses used in studies range from 2.5 to 15 milligrams per day (mg/day).

Atypical Antipsychotics, Fig. 1 Chemical structure of aripiprazole

Atypical Antipsychotics, Fig. 2 Chemical structure of clozapine

Atypical Antipsychotics, Fig. 3 Chemical structure of olanzapine

Side effects of aripiprazole include nausea, weight gain, akathisia, headache, insomnia, agitation, anxiety, and mild transient somnolence.

Clozapine

Clozapine is used in autism spectrum disorders (ASDs) to improve symptoms of aggression. Doses of 276 mg/day in an adolescent and

283.33 mg/day in children have been used to treat ASDs. Side effects of clozapine include a very high risk of sedation; a high risk of anticholinergic effects, sialorrhea, orthostasis, and weight gain; a moderate risk of seizures and hematologic effects; a low risk of increased liver enzyme levels; and a very low risk of extrapyramidal symptoms (EPS) and neuroleptic malignant syndrome (NMS).

Olanzapine

Olanzapine is used in autism spectrum disorders for global improvement of severe behavioral symptoms, overall symptoms of autism, motor restlessness/hyperactivity, social relatedness, affectual relations, sensory responses, language use, self-injurious behaviors, aggression, irritability, anxiety, and depression. The dose for this drug may be between 5 and 20 mg/day and is used in children, adolescents, and adults. Side effects of olanzapine include sedation and weight gain. Also, this drug has a moderate risk of orthostasis and anticholinergic effects; a low, dose-dependent risk of EPS; a low risk of increased liver enzyme levels; and a very low risk of TD, seizures, and hematologic effects.

Paliperidone

Paliperidone has been used in autism spectrum disorders to improve symptoms of irritability, including aggression, self-injurious behaviors, and tantrums. Doses of 6–12 mg/day have been used in adolescents with autism. Side effects of paliperidone include orthostatic hypotension, weight gain, weight loss, and sedation.

Quetiapine

Quetiapine is used in autism spectrum disorders (ASDs) to improve symptoms of aggression,

Atypical Antipsychotics,**Fig. 4** Chemical structure of paliperidone**Atypical Antipsychotics,****Fig. 5** Chemical structure of quetiapine**Atypical Antipsychotics,****Fig. 6** Chemical structure of risperidone**Atypical Antipsychotics,****Fig. 7** Chemical structure of ziprasidone

hyperactivity, and inattention. Doses used in studies of quetiapine for use in the treatment of ASDs include means of 225 mg/day and 477 mg/day in children and adolescents; a mean of 292 mg/day in adolescents; and a mean of 249 mg/day in a group of children, adolescents,

and adults. Side effects of quetiapine include agitation, sedation, weight gain, aggression, and sialorrhea. Also, this drug has a low risk of anticholinergic effects, orthostasis, and increased liver enzyme levels and a very low risk of EPS, NMS, seizures, and hematologic effects.

Risperidone

Risperidone is used in autistic disorder to improve symptoms of aggression, irritability, repetitive behavior and language, hyperactivity, social withdrawal, nonverbal communication, and social responsiveness. An effective dose for children with pervasive developmental disorder (PDD) may range from 1 to 1.2 mg/day, whereas an effective dose for children with autism may be 1.8 mg/day. An effective dose for adults with autism may be 2.9 mg/day. Side effects of risperidone include sedation, increased prolactin, weight gain, and hypersalivation. Also, this drug has a high risk for orthostasis; a moderate, dose-dependent risk of EPS; and a very low risk of tardive dyskinesia (TD), NMS, anticholinergic effects, seizures, hematologic effects, and elevated liver enzyme levels.

Ziprasidone

Ziprasidone is used in autism spectrum disorders to improve symptoms of aggression, irritability, and agitation. A dose used in studies of ziprasidone for use in the treatment of ASDs includes a mean of 59 mg/day in children and adolescents. Side effects of ziprasidone include sedation and mild weight gain. Also, this drug has a low risk of orthostasis and increased liver enzyme levels and a very low risk of EPS, anticholinergic effects, seizures, and hematologic effects.

Atypical Autism

Kylie M. Gray

Centre for Developmental Psychiatry and Psychology, Department of Psychiatry, School of Clinical Sciences at Monash Health, Monash University, Clayton, VIC, Australia

Short Description or Definition

Atypical autism is often described as a subthreshold diagnosis, presenting with some symptoms of autism but insufficient to meet criteria for a diagnosis of childhood autism (or autistic disorder). Alternatively, atypical autism can be diagnosed when there is a late onset of symptomatology. Atypical autism (as defined by ICD-10) is seen as being equivalent to the DSM-IV-TR diagnostic category of pervasive developmental disorder not otherwise specified (PDD NOS). DSM-5 does not have a separate diagnostic category for PDD NOS.

Like PDD NOS, atypical autism is poorly defined, resulting in a research literature that can be difficult to interpret and conclusions difficult to reach. Atypical autism, as defined by the ICD, lacks operationalized diagnostic criteria, resulting in inconsistencies and variability in the way in which the diagnosis is applied. Although it now appears to be more common than autistic disorder, in general it remains poorly understood. This is likely due, in no small part, to the lack of a clear definition. Although it is often assumed that findings relating to autism apply to atypical autism, the lack of operationalized diagnostic criteria has undoubtedly hampered specific research into this diagnostic category and contributed to inconsistent findings across studies. Studies often fail to

describe how they operationalized or defined their samples of atypical autism or PDD NOS. The ICD-10 provides specifiers to further define the diagnosis of atypical autism (see section “[Categorization](#)”); however, studies generally do not use these specifiers. Difficulties therefore remain in interpreting and comparing findings across studies. The broadening of the PDD NOS category in DSM-IV (Volkmar et al. 2000) has also contributed to difficulties in interpretability of results across studies, although with DSM-IV-TR (American Psychiatric Association 2000) this was remedied. Further definition of atypical autism or PDD NOS in research (see, e.g., Mandy et al. (2011)) would assist with furthering knowledge in this area.

This entry will focus on research studies involving individuals with atypical autism. Where necessary, this is supplemented with research findings from samples with PDD NOS.

Categorization

The category of *pervasive developmental disorder* (PDD) was introduced in DSM-III (American Psychiatric Association 1980) and included the subthreshold diagnosis of *atypical PDD*, which subsequently became *pervasive developmental not otherwise specified* (PDD NOS) in DSM-III-R (American Psychiatric Association 1987). Reflecting thinking at the time, ICD-9 categorized autism (299.0 *Infantile Autism*) under the category of childhood psychoses and included a code for *other specified early childhood psychoses*, including *atypical childhood psychosis* (299.8) (World Health Organisation 1978). With the revision of these classification systems to the DSM-IV (American Psychiatric Association 2000) and ICD-10 (World Health Organisation 1992), the systems shared a common approach to coding and were seen as conceptually the same (Volkmar 1998).

The ICD-10 (World Health Organisation 1992) provides diagnostic criteria for *atypical autism* (F84.1) under the category of *pervasive developmental disorders*. The diagnosis is for cases

where age of onset is after the age of three (criteria the same for *childhood autism* except for age of onset), or all three sets of criteria for *childhood autism* are not met (subthreshold). Criteria in the domains of abnormalities in reciprocal social interaction, or communication, or restricted, repetitive, and stereotyped patterns of behavior, interests, and activities are the same as for *childhood autism* (F84.0) except that it is not necessary to meet the criteria for number of areas of abnormality. Specifiers can then be used to indicate *atypicality in age of onset* (F84.10), *atypicality in symptomatology* (F84.11), or *atypicality in both age of onset and symptomatology* (F84.12). The DSM-IV (American Psychiatric Association 2000) defines *PDD NOS* as including atypical autism.

The ICD-10 also has two additional diagnoses, namely, *other pervasive developmental disorder* (F84.8, with no diagnostic criteria specified) and *pervasive developmental disorder, unspecified* (F84.9). The latter disorder is defined as a residual category for cases where there is a lack of information or contradictory findings, but where symptomatology fits the general description for a pervasive developmental disorder. The ICD-10 diagnoses of *atypical autism*, *other pervasive developmental disorder*, and *pervasive developmental disorder, unspecified* are considered to be broadly equivalent to the DSM-IV-TR (American Psychiatric Association 2000) diagnosis of *PDD NOS*.

In the current DSM (DSM-5; American Psychiatric Association 2013), the category of *PDD NOS* has been subsumed under autistic spectrum disorder, with the instruction to give the DSM-5 diagnosis of autism spectrum disorder to those with a well-established diagnosis of *PDD NOS*. Concerns have been raised regarding whether children and adolescents with DSM-IV diagnoses of *PDD NOS* or ICD-10 diagnoses of atypical autism would meet the DSM-5 diagnostic criteria for autism spectrum disorder. Using draft criteria, a number of studies reported concerningly low rates (3–28.3%) of cases of *PDD NOS*/atypical autism meeting the DSM-5 criteria for autism spectrum disorder (Barton et al. 2013; Mandy et al. 2011; Mayes et al. 2013; McPartland et al.

2012). Kim et al. (2014) reported a higher rate (63%) and Huerta and colleagues found that the DSM-5 diagnostic criteria resulted in improved specificity compared to the DSM-IV criteria for *PDD NOS* (Huerta et al. 2012). It has been speculated that children without repetitive, restricted, or stereotyped behaviors previously diagnosed with *PDD NOS* may meet the diagnostic criteria for the new DSM-5 Social Communication Disorder category (Ozonoff 2012; Skuse 2012). Prospective research studies using the DSM-5 diagnostic criteria are needed to explore these issues.

Draft guidelines for ICD-11 (due for release in 2018), mirror the DSM-5, subsuming atypical autism into the single diagnostic category of autism spectrum disorder (WHO, GCP Network 2017).

Epidemiology

Atypical autism is rarely the focus of prevalence studies, and differing labels and combining of groups other than autistic disorder can make the extraction and interpretation of prevalence figures difficult. A number of population and birth cohort studies have included figures on the prevalence of atypical autism. The UK-based studies in children have reported differing prevalence figures of 10.5/10,000 (Lingam et al. 2003), 10.9/10,000 (Williams et al. 2008), and 27/10,000 (Baird et al. 2000), while a birth cohort study (6-year-olds) in Stockholm reported a prevalence of 22/10,000 (Fernell and Gillberg 2010). A study in the Faroe Islands (considered a genetic isolate) reported a population prevalence of atypical autism of 0.12%, while acknowledging that this is possibly an underestimate particularly in terms of higher functioning children (Ellefsen et al. 2007). A Danish population study reported separate prevalence rates for atypical autism (3.3/10,000) and *PDD NOS* (14.6/10,000), which when taken together are similar to those rates reported by Fernell and Gillberg (2010) and Baird et al. (2000). A South Korean study provided a prevalence estimate of 1% for *PDD NOS* (Kim et al. 2011). Using data from the national

Danish register, reported rates of Gender ratios have been reported by a very small number of studies, with a higher proportion of males with autistic disorder compared to atypical autism, 6.5:1 compared to 3.8:1 in Stockholm (Fennell and Gillberg 2010), and no reported gender differences between PDD NOS (85.3% male) and autistic disorder (85.9% male) in a birth cohort of 4–6-year-olds in Stafford in the UK (Chakrabarti and Fombonne 2005).

A series of review studies by Fombonne, most recently in 2009, reviewed 43 prevalence surveys, 17 of which provided separate estimates of the prevalence of atypical autistic syndromes (PDD NOS and atypical autism) (Fombonne 2009). Fourteen of these studies reported a higher prevalence of atypical autism syndromes compared to autistic disorder, 37.1/10,000 and 20.6/10,000 respectively. Like the prevalence of autism, the reported prevalence of atypical autism has increased over time. Similarly, this increase is typically discussed in relation to changes in diagnostic criteria, increased awareness, diagnostic substitution, changes in special education policies, and increases in the availability of services. What is, however, clear from these studies is that there is a significantly large population of children with atypical autism who have treatment needs similar to those of children with autism.

Natural History, Prognostic Factors, Outcomes

A small number of studies have investigated the early signs and symptoms in children later diagnosed with atypical autism, with mixed results. One study looked at first symptoms and diagnosis in children with atypical autism, comparing the parent-reported onset of symptomatology to that of children diagnosed with childhood autism (Oslejskova et al. 2007). Significant group differences were found in age of first symptoms, with parents of children with atypical autism reporting first symptoms at an average of 36.7 months (compared to 23.5 months for children with childhood autism). There were however no significant group differences in age at diagnosis. In contrast,

Walker et al. reported no difference between autism and PDD NOS in terms of age at which abnormalities were first identified by parents (2004). Two epidemiological studies found that atypical autism was diagnosed later than childhood autism, with atypical autism generally diagnosed at 5–6 years of age and childhood autism at 3–4 years (Fennell and Gillberg 2010; Lingam et al. 2003).

Research has demonstrated that outcome in autism and other pervasive developmental disorders is associated with the acquisition of expressive language skills by the age of 5–6 years, cognitive ability, and early social-communicative skills (Gillberg and Steffenburg 1987; Kobayashi et al. 1992; Mundy et al. 1990; Nordin and Gillberg 1998; Sigman and Ruskin 1999). Longitudinal studies have reported that initial diagnosis (i.e., atypical autism or PDD NOS compared to autistic disorder) is not related to outcomes (Baghdadli et al. 2007; Turner et al. 2006) and therefore has limited use in predicting developmental outcomes. However, Moulton et al. (2016) reported that a diagnosis of PDD NOS at age 2 was associated with better outcomes at age 4 relative to those children with a diagnosis of autistic disorder, likely due to lower rates of autism symptomatology, particularly restricted and repetitive behaviors.

Clinical Expression and Pathophysiology

The reliability and stability of the diagnoses of atypical autism and PDD NOS has been questioned. In a study of subtypes of pervasive developmental disorders in children, Mahoney et al. (1998) reported interrater agreement for diagnoses of Asperger's disorder, autism, and atypical autism across three raters. Kappa values revealed good agreement for the diagnosis of autism (0.55), Asperger's disorder (0.56), and non-PDD (0.67), but poor agreement in the case of atypical autism (0.18). Consistent with the results of studies in children with atypical autism, research in toddlers with autism and PDD NOS has reported good agreement between clinicians on the diagnosis of autism, but low rates of

agreement for PDD NOS (Chawarska et al. 2007; Stone et al. 1999).

In relation to diagnostic stability, research has focused on individuals with PDD NOS. While diagnoses of autistic disorder have been shown to be relatively stable in toddlers, the same is not true of PDD NOS (Chawarska et al. 2007; Stone et al. 1999; Turner et al. 2006; van Daalen et al. 2009). A meta-analysis of the diagnostic stability of PDD NOS reviewed eight studies, reporting higher rates of stability for a diagnosis of autistic disorder compared to PDD NOS (Rondeau et al. 2010). It was concluded that a diagnosis of PDD NOS prior to 36 months was unstable (35% stability) over time, highlighting the need for reassessment. It has been suggested that low diagnostic stability may be attributable to the later emergence of stereotyped and repetitive behaviors in young children (Kleinman et al. 2008; Suter et al. 2007).

The lack of operationalized diagnostic criteria for atypical autism and the variability in which the diagnosis is applied have possibly resulted in a significant amount of heterogeneity in the presentation of individuals; as such, there is as yet no consensus regarding the symptom profile for atypical autism or PDD NOS (Mandy et al. 2011). Two studies have examined symptom profiles in children with atypical autism, focusing on high-functioning children with atypical autism, Asperger's disorder, and childhood autism (Kanai et al. 2004; Kurita 1997). In a comparison of children with high-functioning atypical autism and childhood autism, symptom patterns were examined using the Childhood Autism Rating Scale (CARS) (Kurita et al. 1989), rated by clinicians blind to the child's diagnosis. The children with atypical autism scored significantly lower on the CARS total score. There were no significant group differences on 11 of the 15 CARS items. After controlling for IQ and total CARS score, the children with atypical autism were found to be significantly less impaired on two items of the CARS (relationships with people and general impressions) and were more impaired in anxiety reaction compared to the children with childhood autism. In a comparison of high-functioning atypical autism and Asperger's disorder, the Asperger's disorder group was significantly less

impaired than the atypical autism group on total CARS score, imitation, visual responsiveness, auditory responsiveness, and nonverbal communication (Kurita 1997). Overall, these findings are consistent with the idea of atypical autism being a subthreshold diagnosis for children with a significant degree of impairment, but not to the degree that criteria for childhood autism are met.

Further information on symptom presentation comes from studies with children with a diagnosis of PDD NOS. Consistent with the results of the studies with children with atypical autism, a number have reported generally finding children with PDD NOS to have significantly less impairment in the social, communication, and restricted and repetitive symptom domains compared to children with autistic disorder (Fodstad et al. 2009; Walker et al. 2004). de Bruin et al. (2006) reported that children with PDD NOS have similar cognitive profiles as children with autism, although in contrast Walker et al. (2004) found that children with PDD NOS scored better than children with autism on measures of adaptive behavior and nonverbal reasoning and problem-solving skills. An investigation of communication impairments using the Children's Communication Checklist (Bishop 1998) with children with high-functioning autism, Asperger's disorder, and PDD NOS found that while all groups demonstrated significantly more impairment than the typically developing control group, there was little difference across the autism subtypes. In a comprehensive study, Mandy et al. (2011) operationalized the definition of PDD NOS and compared the symptom profiles of children with autistic disorder, Asperger's disorder, and PDD NOS on independent measures of symptomatology. They found that the overwhelming majority (97%) of children with PDD NOS presented with a symptom profile characterized by significant impairment in social interaction and communication skills without repetitive stereotyped behavior. The remaining children presented with a symptom pattern of significant social impairment and repetitive stereotyped behavior without communication impairment. These results are inconsistent with the view of PDD NOS being a condition with marked heterogeneity. The children with

PDD NOS demonstrated significantly less routinized and repetitive behaviors, sensory difficulties, feeding, and visuospatial problems compared to the children with autistic disorder and Asperger's disorder. With PDD NOS now subsumed under the DSM-5 diagnostic category of autism spectrum disorder (ASD), it may be that individuals presenting with marked impairments in social interaction and communication, without repetitive stereotyped behavior, will not meet the DSM-5 diagnostic criteria for ASD.

High rates of comorbid mental health problems have been reported in atypical autism and PDD NOS. A Danish study compared a sample of 89 individuals diagnosed as children with atypical autism to a matched control sample from the general population (Mouridsen et al. 2008). Using the Danish Psychiatric Register, they demonstrated that over a 36-year follow-up period, elevated rates of co-occurring psychiatric diagnoses were found in those with atypical autism. The most prevalent of these was schizophrenia spectrum disorder. High levels of depression, anxiety, and disruptive behavior disorder have been reported in children with PDD NOS (de Bruin et al. 2007; Pearson et al. 2006), highlighting the importance of considering comorbid mental health problems when conducting diagnostic assessments for atypical autism.

It has been reported that while comorbid medical conditions in autism are associated with degree of intellectual disability, they may be more frequent in individuals with atypical autism, although results are mixed across studies (Gillberg and Coleman 1996; Juul-Dam et al. 2001; Rutter et al. 1994). A study by Hara (2007) found no differences between individuals with autism and atypical autism in terms of epilepsy. Biological research on atypical autism and PDD NOS, including neuroimaging and genetic studies, has overall found no evidence for differences between these conditions and autistic disorder (Towbin 2005).

Evaluation and Differential Diagnosis

The assessment process for atypical autism is the same as that recommended for autism and other pervasive developmental disorders. In making a

differential diagnosis, whether the criteria are met for a diagnosis of autism or Asperger's disorder needs to be considered, and degree of intellectual disability needs to be taken into account. Differentiating atypical autism from language disorder is also important. It has been demonstrated that children with PDD NOS can be differentiated from children with language disorders on the basis of more severe social impairment and a greater need for routines and order (Mayes et al. 1993). Research with children with a significant degree of disruptive behavior has also highlighted the need to consider a diagnosis of atypical autism. In a cohort of primary school-aged children, significant impairments in social and communication domains were identified in children with significant disruptive behavior, with 28% meeting criteria for a diagnosis of atypical autism (Donno et al. 2010).

Differentiating ADHD and atypical autism in young children can be problematic, with children often first diagnosed with ADHD (Jensen et al. 1997). In a retrospective study, parents of children with PDD NOS or ADHD reported on the symptoms of their children in their first 4 years (Roeyers et al. 1998). Early differences were infrequent, although children with ADHD showed more hyperactive behaviors during the 7–12-month period; this difference was not maintained as the PDD NOS children became active with age. As children aged, the difference became more apparent, with children with PDD NOS demonstrating more pronounced social difficulties, withdrawal, anxiety, stereotyped motor behaviors, unusual behaviors, and better scores on cognitive assessments compared to children with ADHD (Jensen et al. 1997; Luteijn et al. 2000; Roeyers et al. 1998; Scheirs and Timmers 2009).

Treatment

As for autism, treatment for individuals with atypical autism needs to include a range of services and approaches. Behavioral, educational, and developmental approaches to the treatment of communication deficits, social difficulties, and behavior problems have been demonstrated to

result in improvements for individuals with autism and are likely to be helpful for individuals with atypical autism. Although there are no drugs that specifically treat autism, medication and medication in combination with parent training approaches have been shown to reduce severe behavior problems such as aggression, self-injurious behavior, severe tantrums, and irritability (King 2000; Research Units on Pediatric Psychopharmacology (RUPP) Autism Network 2005a, b, 2009).

Early intervention has been highlighted as a specific area of importance in the treatment of children with autism. Treatment gains have been demonstrated in adaptive functioning, developmental skills, symptom severity, and behavior problems (Dawson et al. 1998; Howlin et al. 2009; Rogers and Vismara 2008). Training parents to implement early intervention programs has also demonstrated gains in communicative behavior, knowledge of autism, parent communication style, parent-child interaction, child behavior problems, and a reduction in parent stress and mental health problems (McConachie and Diggle 2005; Tonge et al. 2006; Whittingham et al. 2009). Improvements can also be made in teaching joint attention, symbolic play, and imitation skills to very young children (Drew et al. 2002; Kasari et al. 2001, 2006). Although important gains have been made in the development of evidence-based early interventions, less is known about the role played by mediating or moderating variables in treatment outcomes. Importantly, the impact that early childhood intervention may or may not have on adult outcomes remains unknown.

Research on treatment approaches specifically for individuals with atypical autism is lacking; it is assumed that treatment needs and approaches are similar to those for individuals with autism.

Whether existing evidence-based treatments produce greater effects in individuals with atypical autism remains an area for further research. As is the case for autism, it has been concluded that no single treatment approach or method has been shown to be effective for PDD NOS (Towbin 2005), with treatment approaches needing to take into account the specific strengths, impairments, and needs of each individual.

Audiovisual Media Content Preferences of Children with Autism Spectrum Disorders

Nicole Martins
Indiana University, Bloomington, IN, USA

Definition

Children with autism spectrum disorder (ASD) spend more time with screen media than any other leisure activity (Shane and Albert 2008). Evidence indicates that children with ASD spend most of their screen time with nonsocial media (i.e., television, video games) and less time with

social media. Compared with other disability groups, among ASD youth, rates of nonsocial media use are higher, and that of social media use are lower (Mazurek 2013b). Similarly, children with ASD report more time with television and video games and less time with social media as compared to neurotypical siblings (Mazurek 2013a). Given that children with ASD report difficulty in developing and maintaining friendships compared to typically developing children (i.e., Rowley et al. 2012), the finding that ASD youth spend more time with nonsocial media is not surprising.

Although existing research demonstrates that children with ASD engage in selective exposure to screen media, less attention has been paid to content preferences among this population. There are only a handful of studies that offer some insight into media content preferences of children with ASD. Regarding television, some studies report that children with ASD tend to prefer animated content (e.g., Martins et al. 2019; Shane and Albert 2008) and that this content is typically created for younger audiences (Martins et al. 2019). Martins et al. (2019) argued that children with ASD select programs with content features made to appeal to developmentally similar children; hence programs for the preschool audience are commonly reported as favorites. These programs are slower-paced and more attuned to specific, individual sensory preferences which may aid in comprehension. Considering that parents identify comprehensibility of content as a key factor in program selection by their children (Martins et al. 2019), then we would expect that these programs are what children with ASD like the most.

Comprehensibility is also a key factor in video game content preferences. In their review, Stiller and Mößle (2018) reported that children with ASD prefer role-playing and simulation games. Martins et al. (2019) argued that games like *Minecraft* are popular among this population because children understand the basic functionality for paying and pausing and have full control over the content they view.

As mentioned above, research demonstrates that children with ASD spend little to no time on social media platforms (Martins et al. 2019; Mazurek 2013a, b). There are at least three

reasons why children with ASD spend less time with nonsocial media. First, children with ASD are socially isolated (Rowley et al. 2012) and may not have a network of friends to connect with online. Second, some apps like *Snapchat* or *Facebook* are not developmentally appropriate, and ASD youth may not understand how such apps work. Finally, parental concerns over the safety of social networks may prevent ASD youth from experimenting with the technology. Parents are worried that their ASD child is incapable of recognizing deceit and therefore might be targets of child predators. Other parents were worried that their child could be made fun or bullied for the content they post (see Martins et al. 2019).

Future research should continue to examine content preferences and how such preferences can be used to teach children both academic and socioemotional skills. For example, future work should test whether education skill could be taught using repeated exposure to preferred components of media (i.e., favorite media characters). Such work is particularly important given that parents report that “autism apps” marketed to the ASD community are either unaffordable or not proven to work (see Martins et al. 2019). Future research should also examine whether restricting access to online communities or social networking apps does more harm than good as ASD children transition into adolescence.

Audition

► [Hearing](#)

Auditory Acuity

Jennifer McCullagh

Department of Communication Disorders,
Southern Connecticut State University, New
Haven, CT, USA

Synonyms

[Hearing sensitivity](#); [Hearing threshold](#)

Definition

Auditory acuity describes how sensitive the auditory system is to sound. Auditory acuity is assessed by determining the intensity at which a tone is just audible. Frequencies important for speech perception are typically tested (octave frequencies from 250 to 8,000 Hz). Normal hearing sensitivity is defined as hearing thresholds from 250 to 8,000 Hz between –10 and 15 dB HL. Hearing sensitivity between 16 and 25 dB HL is considered *minimal* or *borderline*; between 26 and 40 dB HL is considered *mild* hearing loss;

between 41 and 55 dB HL is considered *moderate* hearing loss; between 56 and 70 dB HL is considered *moderately severe* hearing loss; between 71 and 90 dB HL is considered *severe* hearing loss; and greater than 91 dB HL is considered *profound* hearing loss. Hearing sensitivity would be evaluated in an individual with autism spectrum disorders if questions regarding hearing abilities existed, but more systematic research needs to be completed regarding auditory acuity in the population of individuals with autism.

Auditory Brainstem Response (ABR)

Jennifer McCullagh
Department of Communication Disorders,
Southern Connecticut State University, New
Haven, CT, USA

Synonyms

[Brainstem auditory evoked response \(BAER\)](#)

Definition

Auditory brainstem response (ABR), sometimes called brainstem auditory evoked response (BAER), is an electrophysiologic test that assesses the auditory system through the low brainstem. This test can assess hearing sensitivity in individuals who cannot respond to traditional testing; thus, it is often used in newborn hearing screenings and on populations that are nonverbal. The ABR is completed by placing electrodes on the individual's head and ears and placing earphones in their ears. Responses are elicited using click and tonal stimuli which are delivered through the earphones. Five waveforms are typically present in the ABR (waves I, II, III, IV, and V); however, wave V is the waveform used for threshold testing. Individuals with autism spectrum disorders might not be able to consistently respond to traditional tests of hearing sensitivity; therefore, ABR may be useful in establishing hearing sensitivity for these individuals.

Alabama-Birmingham, Birmingham, AL, USA

Synonyms

[Auditory brain area](#)

Definition

The human auditory cortex occupies a large portion of the superior temporal gyrus located along the sylvian fissure dorsally and the superior temporal sulcus ventrally (Brodmann area 41, 42, and 22). The dorsal surface of the superior temporal gyrus is located within the sylvian fissure and is divided into Heschl's gyrus, the planum temporale, and the planum polare. Studies have suggested that the primary auditory cortex in humans is mainly confined to the anterior-medial wall of Heschl's gyrus. This brain region is vital in decoding and processing spoken language and sounds. The planum temporale, also vital in auditory processing, is located posterior to Heschl's gyrus and lies on the superior surface of the posterior superior temporal sulcus. While high-frequency sounds activate a small lateral region anterior to the intersection of Heschl's gyrus and the superior temporal gyrus and a more extensive medial region posterior to the tip of Heschl's gyrus, low-frequency sounds activate lateral regions centered on mid-Heschl's gyrus and extending posteriorly along the superior temporal gyrus.

Neuroimaging research has identified anatomical and functional abnormalities in the planum temporale in individuals with autism spectrum disorder. While anatomical abnormalities include abnormal asymmetry, altered minicolumn organization, and altered cell type and count, the functional abnormalities include abnormal feature extraction and sensitivity to sounds.

Auditory Discrimination

Pamela Heaton

Department of Psychology, University of London,
London, UK

Definition

While enhanced discrimination and memory for musical pitch have been widely described in the literature on musical savants with autism, it is only in more recent times that such abilities have been observed in autistic individuals without savant skills (see Heaton 2003). Bonnel et al. (2010) studied auditory perception in individuals with high-functioning autism and Asperger's syndrome and showed that enhanced pitch discrimination was more prevalent in those with late

speech onset and was not associated with atypical discrimination of stimuli that were spectrally and/or temporally complex. Research identifying enhanced discrimination of pitch change in linguistic stimuli (Jarvinen-Pasley and Heaton 2007) has shown that atypical pitch processing is not limited to music but generalizes across auditory domains. This suggests that difficulties in understanding pitch-mediated linguistic cues or prosody, demonstrated in a number of studies (for review McCann and Peppe 2003), are not perceptual in origin but result from abnormalities in higher-order cognitive operations. Building on the enhanced perceptual functioning model, the neural complexity hypothesis (see Samson et al. 2010) is able to account for enhanced pitch discrimination as well as abnormalities in processing acoustically complex stimuli. According to this model, autism is characterized by a bias toward the perceptual features of auditory information. At the behavioral level, this can be associated with enhanced processing of low-level stimuli and atypical processing of higher-order information, such as greater focus toward the perceptual aspects of speech stimuli.

Auditory Evoked Potential (AEP)

- [Auditory Potentials](#)

Auditory Integration Therapy

Sarita Austin

Unlocking Language, London, UK

Definition

Auditory integration training (AIT) is an intervention technique which is currently considered experimental. It was created to attempt to improve the way individuals with autism spectrum disorders (ASD) recognize and respond to sound and to reduce other behaviors associated with ASD. AIT has also been referred to as auditory enhancement training (AET) and audio-psycho-phonology (APP).

Historical Background

Auditory integration training (AIT) was first written about in 1982 in a book by the otolaryngologist Guy Berard, which was translated in 1993 from French to the English title *Hearing Equals Behavior*. In his writing, Berard suggests that various disorders (“autism,” hyperactivity, depression, learning difficulties) are associated with atypical sensitivity to sound.

The AIT technique became widely popular after the 1991 publication of Annabel Stehli’s *The Sound of a Miracle: A Child’s Triumph over Autism*. In this book, Stehli described the full recovery of her

daughter, who was diagnosed with autism and schizophrenia, after 10 h of AIT at Berard's clinic. In 1994, the American Speech-Language-Hearing Association (ASHA) published a review of the existing data on AIT in response to such accounts linking AIT to increased eye contact, social awareness, verbalizations, auditory comprehension, and articulation and reduced tantrums and hyperacusis (i.e., oversensitivity to certain frequency ranges of sound) in children with autism spectrum disorders, learning difficulties, attention deficit disorder, and dyslexia. Currently, several professional organizations (including the American Speech-Language-Hearing Association, the American Academy of Audiology, the Educational Audiology Association, and the American Academy of Pediatrics) indicate that AIT should be considered an experimental rather than an evidence-based treatment due to the lack of scientific data supporting its benefits.

While in the United States the majority of AIT practitioners use the original Berard or a modified methodology, there are other methods of AIT in existence (including the Tomatis and Clark methods).

Rationale or Underlying Theory

Dr. Guy Berard, an ear, nose, and throat (ENT) physician, first introduced auditory integration training (AIT) suggesting that many learning and behavioral disorders, "including autism," are associated with hypersensitivity to sound at particular frequencies possibly resulting in disturbances in learning and discomfort. He suggested that although many children with autism spectrum disorders (ASD) can hear sound, the way in which they process sounds is different and can result in reduced emotional responsiveness and repetitive behaviors even if hypersensitivity to sound does not exist.

Goals and Objectives

In 1982, Dr. Berard suggested that auditory integration training (AIT) would involve a

"reeducation" of the hearing process for individuals with autism spectrum disorders (ASD) targeting the atypical sound perception theorized to be present in a variety of behavioral and learning disorders. Specifically, he suggests the training of the middle ear muscles, and the auditory nervous system is targeted through listening exercises.

Treatment Participants

Auditory integration training (AIT) has been promoted by Dr. Berard as a useful intervention for a variety of disorders (e.g., learning disabilities, behavior disorders, autism, pervasive developmental disorder, attention deficit disorder, attention deficit hyperactivity disorder, tinnitus, progressive deafness, hyperacusis, allergic disorders, depression, suicidal tendencies, poor organizational skills) and has also been recommended for reducing foreign accents and writer's block.

Treatment Procedures

Auditory integration training (AIT) begins with an audiogram (i.e., a graph showing the results of a pure-tone hearing test) to determine whether auditory "abnormalities" exist. The treatment involves ten consecutive days of therapy centered upon listening to music (that has been modified to dampen certain sound frequencies and intensities to correspond to those found abnormal on the audiogram) for 30 min twice a day. It is recommended that sessions occurring on the same day be separated by at least 3 h, while a 2-day interruption of therapy on weekends is allowed.

Audiograms are also used to determine if filter settings need to be adjusted mid-intervention and to monitor response to treatment post-intervention. Berard asserts that following AIT, audiograms show that auditory distortions are eliminated, as they become "flattened." He explains that the "peaks and valleys" in the original audiograms reflect areas of hyper- and hypo-sensitivity, but there is debate as to whether these patterns truly indicate auditory "abnormalities."

Following the recommended 20 auditory integration therapy (AIT) sessions in Dr. Berard's method, an audiogram is obtained and reviewed, while changes in behavior patterns are examined to measure outcome. In efficacy studies of AIT, outcome measures have included post-intervention assessments in the following areas: cognitive ability, core features of autism (i.e., social interaction, communication, and behavioral problems), hyperacusis, auditory processing, behavioral problems, attention and concentration, activity level, quality of life in school and at home, and adverse events.

The US Food and Drug Administration (FDA) banned the import of the Berard's original equipment (Audiokinetrone or Ears Education and Retraining System) used for AIT as a medical device based on finding that there was no sufficient evidence to support that it benefited individuals medically. The FDA regards the Audiokinetrone as an educational aid but not appropriate for the treatment or curing of any medical conditions, such as autism spectrum disorders. The Digital Auditory Aerobics (DAA) device was introduced as a result of this limited access to the Audiokinetrone in the United States. The 20 compact disks (CDs) (each containing 30 min of modulated music) available with this device are believed to match the output of the Audiokinetrone device. Other AIT programs are available (e.g., Samonas Sound Therapy, The Listening Program) which provide music on CDs and promise similar results to Berard's AIT programs.

Efficacy Information

The efficacy of auditory integration training (AIT) continues to be debated. A review of the available existing research indicates that three studies suggest improvements with AIT at 3 months post-intervention based on reported improved performance scores on the *Aberrant Behavior Checklist*. It should be noted that investigators in these studies were associated with organizations that promote or directly provide AIT. Similar results have not yet been replicated by any independent studies. The review highlights the fact that the studies examining

AIT were not randomized controlled trials (used to minimize bias), did not contain control or alternative treatment group, and involved single or very few participants or used surveys or animals.

The American Speech-Language-Hearing Association (ASHA) issued a report on AIT, in which it states that further research in AIT is discouraged given the lack of evidence that it is an effective treatment for individuals with autism spectrum disorder (ASD) but indicates that a "high level of evidence" of its efficacy should be provided if future AIT trials are conducted. ASHA also cautioned parents to take precautions to avoid hearing loss while also being aware of the costs involved in receiving AIT. In studies where children or adults with ASD (ages 3–39 years) were selected and randomly assigned to study treatment groups, though no adverse effects were reported, no noteworthy changes were found in the participants' ability to process sound, their quality of life, or their core and associated features of ASD following AIT. ASHA expressed concerns that clear criteria (based on evidence-based research) are not available, indicating which individuals will be most appropriate for AIT, and families could find both their financial resources and hope strained or depleted by investing in interventions that lack empirical support. In addition, the professional organization had reservations regarding the variability in AIT treatment protocols and the possible noise-induced hearing loss that might be associated with AIT devices, as sufficient data on the risk to participants regarding intensity of sound and length of presentation is not currently available for the devices. In more recent studies (2013–2016), electrophysiological changes and behavioral changes via caregiver report were observed in children with ASD following a series of AIT sessions. Authors of these studies suggested further research to explain the neural mechanisms of how AIT may affect such changes. Still, studies during this same time period suggested the lack of efficacy of AIT, some suggesting increased occurrence of stereotypy post-AIT.

Considering that ASD behaviors can often resemble auditory processing disorders (APD), ASHA has also ruled out the diagnosis of APD, for which AIT is often suggested, in children with

ASD unless reliable testing reveals deficits on multiple assessments. In the case that a child with ASD does meet this guideline, the benefit of receiving intervention involving listening tasks with limited social interaction can also be questioned.

Qualifications of Treatment Providers

The majority of auditory integration training (AIT) practitioners are speech-language pathologists or audiologists but have also included psychologists, physicians, social workers, and teachers. No training is required to operate the Digital Auditory Aerobics (DAA) device that is currently used within the United States to provide AIT based on Berard's method. Other AIT programs do provide trainings to practitioners (e.g., The Listening Program [2½ days], Samonas Sound Therapy [offers a credentialing process following pre-workshop training, initial and advanced workshop training, and a year of practice]). The American Speech-Language-Hearing Association, the American Academy of Audiology, the Educational Audiology Association, and the American Academy of Pediatrics nonetheless all state that AIT should be considered an experimental rather than an evidence-based treatment due to the limited amount of scientific research studies supporting its benefits.

Definition

An auditory potential is an electroencephalographic (EEG) response, less than a millivolt, time-locked to an auditory sound such as a click, tone, or speech sound. It is recorded from scalp electrodes and consists of averaged responses to a series of sounds. Averaging removes background EEG activity, usually considered to be unrelated to the auditory potential.

A brief sound such as a click triggers at least 15 waveform peaks that unfold over the first second (Picton et al. 1974). These alternating positive and negative peaks reflect the flow of auditory information from the brainstem to the cortex. The short-latency peaks appearing during the first tenth of a second (10 ms) originate from the primary auditory pathway of the brainstem.

Central Auditory Processing Disorders (CAPDs) were described in early 1940s and have recently become of interest to ASD researchers (see Ocak et al. 2018). Auditory middle latency responses are promising auditory tests that allow the identification of functional deficits of the central auditory pathways, and the cerebral hemispheres in school children with reading and writing learning disorders. The recording of these potentials ensure visualization of the electrical activity of the primary auditory cortex and the auditory thalamus-cortical pathways, from the observation of a sequence of waves, negative (N) and positive (P). Na, Pa, Nb, Pb occur in 10–80 ms intervals after stimuli (McPherson et al. 2008).

The later auditory potentials, a subset of event-related potentials (ERPs), represent the sum of neural activity originating from spatially distinct sources. They are usually studied with multiple scalp electrodes that enable determination of waveform scalp topography. Mid-latency auditory peaks, which appear during the 10–50-ms interval, have few well-established clinical findings. Attention effects are seen under some conditions during the later part of this interval.

Long-latency peaks appearing between 50 and 1,000 ms have received the most study. The specific timing of these peaks depends on both the auditory stimulus characteristics and the task demands. They are named starting with the

initial positive peak (P1) at 50 ms usually maximal at the frontocentral electrodes. Next is the negative peak (N1) at around 100 ms, maximal at the vertex. P2 peaks at 150–200 ms. The negative peak (N2) is typically maximal at 200–300 ms at central sites. The P3 peak at 300–400 ms is attention dependent. Amplitude is inversely related to stimulus probability, and latency is positively related to task difficulty. Developmentally, the scalp location of the maximum depends on task conditions.

These waveform peaks each reflect several underlying components. The waveform peaks should be distinguished from the components, which refer to potential neural sources. Unless the component is large such as P3b, it usually needs to be isolated with difference waves or by experimental design (Luck 2005). The component peaks are often identified by the number of milliseconds to peak, e.g., N75 and P100. Auditory ERPs are also used to study language processing. An N400 component, maximal over central and parietal sites, is seen when there is a semantic deviation from expectations, e.g., the last word in a sentence is out of context. P3a, P3b, and N400 components do not appear before ages 3 or 4 years. A central, frontal negative component, at 400–500 ms, reflecting attention has been identified in early infants and labeled “Nc.” A recent review concluded that persons with autism show differences in many of the long-latency components (Jeste and Nelson 2009).

Central Auditory Processing Disorder (CAPD)

Short Description or Definition

Central auditory processing disorder (CAPD) may be considered when a child is having difficulties producing or understanding verbal language. Lack of appropriate response to what others say may cause people to think the child may be deaf; however, audiological examination of children with CAPD is entirely normal. These children can hear and detect sounds, but their ability to process these sounds meaningfully is not developing as expected. These children may have difficulty recognizing sounds or discriminating between different sounds. CAPD is a controversial diagnosis that is not currently part of conventional diagnostic systems but is increasingly identified in the USA and

Australia and to a more limited extent in the UK and rest of Europe. According to the American Speech-Language-Hearing Association (ASHA) (2005), CAPD refers to difficulties in the perceptual processing of auditory information in the central nervous system and is demonstrated by poor performance in one or more of the following tasks: sound localization and lateralization; auditory discrimination; auditory pattern recognition; temporal aspects of audition, including temporal integration, temporal discrimination (e.g., temporal gap detection), temporal ordering, and temporal masking; auditory performance in competing acoustic signals (including dichotic listening); and auditory performance with degraded acoustic signals. Despite this characterization, there remains little professional agreement about how CAPD should be defined, diagnosed, or treated (Dawes and Bishop 2009).

Epidemiology

There are currently no epidemiological data concerning CAPD in children.

Natural History, Prognostic Factors, and Outcomes

There are currently no longitudinal studies of children with CAPD with which to address questions of history, prognosis, or adult outcomes.

Clinical Expression and Pathophysiology

Reported symptoms of CAPD may include difficulties understanding speech in noise, difficulties following or understanding verbal instructions, poor attention and high distractibility, and communication, language, reading, and academic difficulties.

Evaluation and Differential Diagnosis

ASHA (2005) best practice guidelines recommend diagnosis by a multidisciplinary team that includes a minimum of an audiologist and a

speech-language pathologist. Peripheral hearing should be thoroughly investigated using hearing thresholds, immittance measures, and otoacoustic emissions (Dawes and Bishop 2009). There are, however, no firm guidelines as to what standardized tests of auditory processing should be included, how many tests are required to tap the range of skills that may be compromised, or what cutoff would be indicative of a clinically significant impairment in central auditory functioning.

Part of the controversy surrounding this disorder appears to stem from the methods of assessment and the degree to which they involve speech stimuli (Dawes and Bishop 2009). When such tasks are included, it is difficult to ascertain the origin of the problem: If a child's language is impaired, he or she might perform poorly on tests of speech discrimination in noise because of limitations in linguistic ability rather than a central auditory processing disorder. On the other hand, many language-based tasks will require the auditory processing abilities listed above. ASHA (2005) clarifies the situation to some extent by stating:

although abilities such as phonological awareness, attention to and memory for auditory information, auditory synthesis, comprehension and interpretation of auditorily presented information, and similar skills may be reliant on or associated with intact central auditory function, they are considered higher order cognitive-communicative and/or language-related functions and, thus, are not included in the definition of CAPD.

Differential diagnosis is a clinical concern; Dawes and Bishop (2009) point out that 50% of children meeting criteria for CAPD also meet criteria for other developmental disorders such as ADHD, autism spectrum disorder (ASD), or specific language impairment (SLI). The degree of overlap raises issues about CAPD as a coherent diagnostic entity, and some have argued that the choice of diagnostic label reflects the conceptualization of the problem by the professional assessing the child (Ferguson et al. 2011). In other words, a child with poor attention and language delay may be diagnosed with CAPD by an audiologist, DLD by a speech-language pathologist, or ADHD/ASD by a clinical psychologist.

The difficulty is in determining the nature of the relationship between auditory processing difficulties and the developmental disorders associated with those difficulties. For example, if a child presents with delayed language development, it may be reasonable to assume that these language difficulties are the result of difficulties processing sound. However, as noted above, language difficulties may interfere with the child's ability to do tasks that assess auditory perceptual performance. Equally, there may be a third factor that disrupts both language development and auditory processing, yielding a strong association between the two even though they may be causally unrelated (see Bishop 2011 for discussion).

Tests of CAPD frequently require children to make judgments about sounds; even when the stimuli are tones rather than speech sounds, language ability may affect performance. For example, Marshall et al. (2001) reported that many typically developing children spontaneously adopted a strategy of labeling tones as "high" or "low" and that this labeling facilitated performance on similarity judgment tasks. Thus, children with SLI may be disadvantaged on assessments of CAPD, though it is the case that a substantial minority of children with SLI do experience auditory difficulties (see Dawes and Bishop 2009). It is less clear that these auditory difficulties are causally related to language impairment, though feasibly that may contribute to language learning difficulties (Bishop 2011). However, it is also clear that many children diagnosed with CAPD have considerable language difficulties and often do not differ from children with SLI with regard to language and cognitive profile (Ferguson et al. 2011). These findings again raise the question of whether these are diagnostically and etiologically distinct categories or whether they reflect professional biases.

These tasks also require children to listen carefully and attend to subtle sound differences over a large number of trials. Even typically developed children may find this challenging; for children with ADHD, it may be impossible. In order to differentiate CAPD and ADHD, Dawes and Bishop (2009) advocate the use of behavioral measures that tap visual attention. The prediction

would be that children with ADHD would have difficulties across modalities, whereas children with CAPD would be impaired only on the auditory tests. The more difficult issue to tease apart is whether performance on either measure by children with ADHD reflects attention skills or is indicative of a central processing disorder.

With regard to ASD, perceptual anomalies are frequently reported in both research and clinical settings, though again these are rarely confined to the auditory modality. In addition, the child with ASD is likely to have social deficits that may mimic auditory disorder. For example, not responding to parents calling the child's name is an early indicator of ASD but may also signal an auditory deficit. Dawes and Bishop (2009) reported that children with ASD are overrepresented at assessment centers specializing in CAPD. Research studies that use electrophysiological techniques (e.g., ERP) have suggested that the auditory impairments that characterize ASD arise because of a speech-specific, postsensory impairment related to attentional orienting (Ceponiene et al. 2003; Whitehouse and Bishop 2008). Dawes and Bishop (2009) further suggested that such top-down influences on auditory processing would require a different treatment approach to developing listening skills from the treatments recommended for CAPD.

In sum, it is likely that auditory processing problems are one of a number of "collateral" deficits commonly found in across a range of neurodevelopmental disorders (Dawes and Bishop 2009). Thus, assessment in a multidisciplinary setting will be necessary for documenting auditory deficits and considering these deficits in relation to the child's overall cognitive, linguistic, and social profile. Where possible, assessment of auditory skills that do not explicitly involve speech-based stimuli is preferable in order to avoid the confounding effects of impaired language development.

Treatment

Bishop (2011) highlighted the importance of establishing the causal role of auditory processing

in other developmental disorders because of the implications for treatment. If auditory difficulties contribute to attention or language difficulties, then it would make sense to train auditory skills with positive downstream effects for language and attention. However, if auditory deficits are associated, but do not play a causal role in disorder, such treatments would not be effective. Several computer-based training packages have been developed, with Fast ForWord (Scientific Learning Corporation) being the most popular and widely used in clinical and education contexts. This program was not specifically designed for CAPD but is based on a theoretical framework in which development language and literacy learning difficulties arise from impairments in rapid auditory temporal processing (Tallal and Piercy 1973). Fast ForWord is comprised of adaptive computer games that include acoustically modified speech; the degree of modification gradually diminishes as the child improves performance on the language-based tasks. It is most widely used for children diagnosed with SLI or dyslexia; however, rigorous trials of Fast ForWord and similar computer-based intensive auditory training have not yielded clinically significant improvements in language or literacy functioning (Loo et al. 2010; Strong et al. 2011).

There is currently a dearth of studies investigating treatment efficacy for children diagnosed with CAPD. For the most part, Dawes and Bishop (2009) report that current clinical practices do not aim to treat the auditory deficit directly, but rather aim to reduce the impact of auditory processing deficits through environmental modification (e.g., sitting the child nearer to the classroom teacher, waiting to have the child's visual attention before speaking) or by enhancing the auditory signal (e.g., using a directional microphone in the classroom). However, the effect of these modifications on developing auditory skills or improving language and academic outcomes is largely unknown.

Definition

The auditory system includes the outer, middle, and inner ears, as well as the central auditory nervous system. The outer ear includes the pinna and the external auditory meatus (ear canal). The tympanic membrane (eardrum) is the boundary between the outer and middle ear. The middle ear is housed in the mastoid portion of the temporal bone and is a completely enclosed cavity that is connected to the nasopharynx by the Eustachian tube. The middle ear houses the three smallest bones in the body, the malleus, incus, and stapes, also known as the ossicular chain. The inner ear is called the cochlea, which contains the sensory hair cells and auditory nerve fiber endings that convert mechanical energy from the middle ear into electrical energy. The VIII cranial nerve, vestibulocochlear nerve, brings the auditory information to the central auditory nervous system which consists of the brainstem nuclei (cochlear nuclei, superior olivary complex, lateral lemniscus, inferior colliculus, and medial geniculate body), the primary auditory cortex in the temporal lobe and the association auditory cortices.

The entire auditory system codes frequency, intensity, and time which are essential to the perception of sound and therefore speech.

Auditory Verbal Learning

Laura B. Silverman and Allison R. Canfield
Department of Pediatrics, University of
Rochester, School of Medicine and Dentistry,
Rochester, NY, USA

Definition

Auditory verbal learning refers to the process of acquiring and retaining new information about the sound patterns and/or meanings of words, sentences, stories, and other nonword sequences, after hearing them read aloud. A person's ability to learn the underlying sound structures and meanings of words creates the foundation for that person's ability to ultimately understand speech and use language to communicate with others. One of the core features of ASD is "a

delay in, or total lack of, the development of spoken language” (American Psychiatric Association 2000). Thus, characterizing the strategies that people develop and use to learn language during auditory verbal learning tasks could help to illuminate the mechanisms underlying communication skills in autism.

Historical Background

Research on auditory verbal learning began with the seminal work of Hermann Ebbinghaus, in the late 1800s. Ebbinghaus believed that learning verbal material required the formation of new associations between words. He also posited that the strength of these associations could be intensified with repeated exposure and practice. Thus, he designed a research program to test this hypothesis, using himself as a research subject. He developed lists of “nonsense syllables,” which consisted of consonant-vowel-consonant combinations that have no specific meanings associated with them. For example, DAX and YAT would be considered nonsense syllables, since they are not words in the English language. CAT would not be a nonsense syllable since it has a known meaning. Ebbinghaus attempted to learn his lists of nonsense syllables by slowly reading and repeating the lists to himself. Next, Ebbinghaus tried to recall as many of the syllables as he could. He discovered that his memory for the syllables improved with repeated practice of the material. In addition, he noted that his ability to learn the syllables initially improved rapidly and then more slowly over time, until he learned the material in its entirety. By characterizing these patterns, Ebbinghaus was the first to identify and map out verbal learning curves (patterns of learning over time and with repetition). He similarly identified patterns of forgetting over time and found that forgetting occurs less quickly, when the material is overlearned (repeatedly practiced, even after achieving perfect recall of the list). In addition, Ebbinghaus examined *serial position effects* and discovered that words are easier to learn at the beginning and end of a verbal learning list.

Research on auditory verbal learning continued into the twentieth century, heavily influenced by Ebbinghaus’ work and also by behaviorism, with a focus on stimulus–response aspects of language learning. Then in the 1950s and 1960s there was a shift to studying cognitive “mediators,” which were thought to be conscious mental processes that can be deployed to improve verbal learning performance. This shift was heavily influenced by verbal mediation theory and cognitive psychology, which examined internal cognitive processes rather than focusing specifically on observable behaviors. In the late 1960s and 1970s, John Flavell extended findings related to verbal mediation and described verbal learning abilities from a developmental standpoint, proposing that younger children have more trouble learning verbal information than older individuals because they have a *production deficiency*. In other words, younger children fail to spontaneously produce and use strategies to improve their performance. It was noted these children often showed significant improvements on auditory verbal learning tasks, once they were directly instructed to use specific strategies. For example, Flavell found that younger children were less likely to verbally repeat words to themselves while learning the words from a list, while older children were more likely to use verbal rehearsal with increasing age, and the spontaneous use of this strategy was associated with improvements on task performance.

Flavell’s research initiated a flurry of subsequent training studies examining whether direct instruction in strategy use improved children’s auditory verbal learning abilities. In other words, researchers took children who were not yet actively using strategies on their own and set out to see whether prompting them to use rehearsal, organization, and elaboration improved verbal learning ability. Overall, they found that the ability to use learning strategies typically develops in broad strokes throughout childhood, adolescence, and early adulthood. For example, there are gradual developmental increases in the ability to use semantic strategies and word meaning to aid verbal learning, from the preschool years through adolescence. These advancements in semantic

strategy use are generally accompanied by related improvements in verbal recall performance. Children often begin using word meaning to facilitate verbal learning during elementary school, and as preadolescents they are more likely to use semantic strategies successfully when tasks include words with strong associated meanings, and when there are directions that explicitly instruct them to use these strategies. By adulthood people can use word meaning to facilitate verbal learning, even when there are no explicit directions to do so, and when words are more subtly semantically related to one another. Similarly, verbal rehearsal also changes across development, with younger children rehearsing single words repetitively, while older adolescents rehearse multiple words in clusters. This shift from single-word to multi-word rehearsal is also associated with improved auditory verbal learning performance.

Current Knowledge

In the late 1960s researchers began examining how children with ASD learn words and more complex verbal information. This interest stemmed from the observation that individuals with ASD could engage in echolalia and use stereotyped language without necessarily understanding the core meaning of the words that they echoed. The ability to learn the sound patterns but not the meaning of words was surprising since typically developing people found it easier to learn meaningful information compared to meaningless sets of words or sound strings (Marks and Miller 1964).

Using Word Meaning to Improve Learning: Semantic Strategies

Hermelin and O'Connor were among the first to examine the relationship between word meaning and auditory verbal learning abilities in ASD. They did so by comparing children with ASD and those without ASD on their ability to learn and immediately recall verbal information with varying semantic relationships. They presented children with meaningless word strings and

meaningful sentences. They were asked to recall as much as they could remember, in each condition. Children without autism remembered significantly more sentences than word strings, while children with ASD did not show more efficient learning of meaningful information. Researchers also read children strings of unrelated words and strings of related words from a shared semantic category, such as colors or utensils. Children with ASD were much less likely to group words together from the same category than children without autism. Collectively, these studies suggest that children with ASD were less likely to use word meaning to aid auditory verbal learning. They were also more likely to rely on phonological features or sound patterns of the words rather than word meaning. It is important to note that these early studies primarily involved children who had ASD and intellectual disability. Subsequent research looked at both high- and low-functioning individuals with ASD; although studies yielded mixed findings, they generally support the observation that people with ASD are less likely than those without ASD to use word meaning to improve learning and memory of verbal information.

Using Word Order to Improve Learning: Primacy and Recency Effects

The location and order of words within a word-learning list can also be used to improve auditory verbal learning skills. Scientists have studied whether individuals remember certain parts of a list more readily than other parts, and whether recalling words from the beginning, middle, or end of a list is associated with better learning and memory overall. Remembering words from the beginning or first portion of a list is referred to as the primacy effect. This pattern of recall is thought to reflect the active use of verbal rehearsal, a strategy that involves repeating words over and over again to facilitate retention. Verbal rehearsal has been shown to improve auditory verbal learning in typically developing individuals. Conversely, remembering words from the end of a word list is often referred to as a recency effect, and is thought to reflect a more shallow

level of processing that involves simply echoing back the sounds that were most recently heard. Low-functioning individuals with ASD tend to rely more heavily on rote memory abilities and are more likely than people without autism to simply echo back words from the end of a list. In other words they tend to show a stronger recency effect than people without ASD. This suggests that they rely on more simple and less efficient learning strategies than individuals without autism, who are more likely to use verbal rehearsal to aid learning. Individuals who are high-functioning with ASD show a different pattern of verbal learning and memory. They have demonstrated typical primacy and recency effects when compared to people without autism. The degree to which individuals with autism group words together, based on order, varies across studies; some research has found typical serial position effects while other studies have not. Although overall, individuals with autism appear less able to actively deploy learning strategies efficiently to support their verbal learning.

Using Repetition to Improve Learning: Learning Curves and Retention over Time

To examine auditory verbal learning over time, researchers have used experimental paradigms that involve reading a single list of words over a series of repeated trials. Verbal learning curves are quantified over time to determine how much new information an individual retains with each repetition of the verbal material. Some researchers have used the California Verbal Learning Test (CVLT; a standardized measure of verbal learning and memory) to examine the rate of verbal learning in ASD compared to controls. During the CVLT participants hear a single list of nouns read aloud on five consecutive learning trials. After each trial, participants are asked to immediately recall as many words as they remember. The list has a fixed word order and an underlying semantic structure, meaning that each word on the list belongs to one of a few semantic categories, such as fruits or furniture. When compared to people without ASD, adolescents and adults with high-functioning ASD show typical rates of

verbal learning on early learning trials and poorer recall on later trials. This suggests less efficient auditory verbal learning over time. In other words, their ability to learn new verbal information over time slows down more quickly over repeated trials in comparison to people without ASD. In addition, individuals with ASD were less likely to cluster words together based on shared semantic categories or the order in which they appeared in the original list. In this case, slower learning was likely attributable to less efficient use of learning strategies over time.

To summarize our current knowledge, the research to date suggests some general trends in auditory verbal learning abilities in ASD. First, individuals with ASD are less likely than people without ASD to use word meaning and semantic structure to enhance their learning abilities. Second, they are also less likely to use other active learning strategies, like verbal rehearsal and serial clustering. Finally, when word lists are read repeatedly, individuals with ASD tend to learn words less efficiently over time. Although these are general trends observed in the research literature, patterns of auditory verbal learning have not been entirely consistent across all studies, and these trends are observed more often in low-functioning individuals than in higher-functioning individuals with ASD.

Future Directions

There are a number of possible avenues for future research on auditory verbal learning in ASD. First, future research could adopt a developmental perspective, using longitudinal studies that examine auditory verbal learning abilities as people age and develop throughout their lifespan. Our knowledge about auditory verbal learning in ASD comes largely from cross-sectional studies, which provide a snapshot of verbal learning abilities by capturing performance at a single time point in a person's life. Larger scale longitudinal studies focusing on the emergence and active use of different types of verbal learning strategies at multiple points within a person's life would help

to identify whether specific patterns of learning are simply delayed in ASD or whether they remain consistently impaired throughout the lifespan. Knowing more about the development and use of learning strategies and auditory verbal learning skills over time could help to shape interventions designed to improve verbal learning and communication in this population.

In the same vein, training studies could be conducted to explicitly instruct individuals with ASD to use strategies known to improve auditory verbal learning performance. Such studies could help to evaluate whether explicit instruction on strategy use would improve verbal learning in the short term. In addition, this line of research would also help to determine whether improvements due to instruction could be sustained over time, without additional instruction and maintenance.

Finally, there has been considerable theorizing about underlying neurobiological mechanisms responsible for impaired auditory verbal learning in ASD. In particular, temporal and frontal lobe regions have been implicated, as well as more distributed problems with connectivity. Most studies investigating auditory verbal learning in ASD compare performance on list-learning tasks in individuals with ASD to patterns of performance in individuals with known brain lesions. This approach provides a starting point for identifying underlying neural mechanisms. However, future research could extend this research by utilizing imaging techniques to identify patterns of brain activation during verbal learning tasks in individuals with ASD, and to specify whether particular regions of the brain are related to less efficient verbal learning in this population.

Augmentative and Assistive Technology

Maureen Nevers
Center on Disability and Community Inclusion,
University of Vermont, Burlington, VT, USA
Augmentative Communication Consultant,
Center on Disability and Community Inclusion,
Burlington, VT, USA

Definition

Assistive technology A broad range of devices, services, strategies, and practices that address the

problems faced by individuals who have disabilities (Cook and Polgar 2008)

Assistive technology device “Any item, piece of equipment, or product system, whether acquired commercially off the shelf, modified, or customized, that is used to increase, maintain, or improve functional capabilities of individuals with disabilities” (Assistive Technology Act of 2004)

Assistive technology service “Any service that directly assists an individual with a disability in the selection, acquisition, or use of an assistive technology device” (Assistive Technology Act of 2004)

Augmentative and alternative communication (AAC) One type of assistive technology that specifically focuses on the strategies, interventions, and supports that assist a person with a disability to communicate

Historical Background

In 1988 the Technology-Related Assistance for Individuals with Disabilities Act (1988), called the Tech Act, provided support for activities to help individuals with disabilities to obtain assistive devices and services. The Tech Act focused on helping states create systems that would give individuals with disabilities improved access to assistive technology devices (Bausch et al. 2005). In 2004 the Assistive Technology Act, called the AT Act, continued support for the systems established by the earlier legislation. The AT Act also recognized that “there is a continued need to provide information about the availability of assistive technology, advances in improving accessibility and functionality of assistive technology, and appropriate methods to secure and utilize assistive technology. . .” (AT Act 2004). The new law required majority of states’ funding that was to be used specifically for programs

focusing on assistive technology reutilization, demonstration, and device loans (AT Act 2004).

Both the Individuals with Disabilities Education Act of 2004 (IDEA) and Rehabilitation Act of 1973 speak to the provision of assistive technology in school. IDEA states that assistive technology devices and services must be made available “if required as a part of the child’s special education, related services or supplementary aids and services” (2004). While IDEA uses the AT Act terminology in its definition of assistive technology, it also more specifically outlines the responsibilities related to application in the educational setting. The Rehabilitation Act of 1973 ensures that students who do not qualify for special education but require AT are still provided access to those supports and services.

Current Knowledge

Assistive technology (AT) has been integrated into our work, home, school, and community through programs that focus on identifying, obtaining, and using assistive technology in order to maximize the independence and participation of individuals with disabilities in society (Tech Act 1988). This process of matching the person with a disability, the activity or task, and the assistive technology device is outlined in the definition of assistive technology service found in the AT Act (2004). The types of activities that are part of assistive technology service include evaluation of AT needs of the person, including in relevant and functional environments; procuring the device; conducting tasks associated with obtaining and maintaining the proper device; coordinating different stakeholders to support the assistive technology; training or technical assistance; and expanding access to AT (AT Act 2004).

The definition of a person with a disability, according to the Americans with Disabilities Act, is “a person who has a physical or mental impairment that substantially limits one or more major life activities” (ADA n.d.). In order to access the available AT resources, an individual with autism spectrum disorder or other disabilities will need the support of knowledgeable team

members who can be actively involved in the AT evaluation and implementation. The team can now move toward the identification of appropriate AT tools, training, and technical assistance necessary to increase the person’s abilities to successfully participate in a range of life activities as independently as possible.

The qualifications of the evaluation team members are not specified in the law, but at a minimum the team should be able to execute the steps of an assistive technology assessment including identifying the relevant strengths and challenges of the individual knowledgeable about the range of AT options that are available for consideration (OCALI 2013). AT services are provided by professionals in a number of different fields, such as speech pathology, occupational therapy, physical therapy, engineering, and special education. The law does not require evaluators to have specific credentials; the Rehabilitation Engineering and Assistive Technology Society of North America (RESNA) has developed a certification program so that professionals from related fields can be certified as an Assistive Technology Professional (ATP). ATPs are skilled with evaluating the needs of individuals, matching them to AT, and helping with training in implementation. RESNA has also identified standards of practice in the field of assistive technology which guide the work of ATPs for consistency and fidelity.

Consideration of a person’s assistive technology needs requires an understanding of the user’s abilities and challenges, the context for application, and relevant experiences with other AT supports and strategies. The World Health Organization refers to the term disability as “reflecting the interaction between features of a person’s body and features of the society in which he or she lives” (WHO). This definition highlights the relationship between a person’s abilities and the performance expectations as opposed to a specific diagnosis. The elements of the assessment of the person’s strengths and difficulties are not prescribed by law. Evaluation teams may assess the person’s vision and hearing abilities, as well as their mobility, cognition, learning, communication, and social skills. To understand the impact of the disability fully, functional contexts must be

included in the evaluation. Some other major life activities that could be observed are recreation, daily living, self-care, and working. Activities such as reading, concentrating, standing, lifting, bending, and others (ADA 2011) represent an even broader interpretation of potential applications of assistive technology (Pacer).

Selecting assistive technology is a dynamic process of matching the task, the person, and the tool. There are many resources available online and in texts to guide teams through the process of assessing the need for assistive technology, such as the SETT process (Zabala 2005e), the Wisconsin Assistive Technology Initiative (WATI 2009a), and OCALI AT Resources (2013). In addition to information about specific AT devices, these documents also outline a sequence of steps for an AT evaluation, such as the one from OCALI (2013) below:

1. What are the specific tasks the person needs to perform?
2. What barriers exist, and what is the impact on the person's participation in the task?
3. What strategies and tools have been tried, and what were the results?
4. What AT tools or strategies might be useful in overcoming these barriers or challenges?
5. What is the plan for implementation of the identified AT solutions?

What are the specific tasks the person needs to perform? The identification of appropriate AT starts with determining where and when the AT is needed. Activities that may require AT supports cover all aspects of life, including daily living, vocational, educational, recreational, and social activities (Reed 2009). Within each of these activities, consider the specific tasks that the person wants or needs to perform. These environments and the expectations associated with them represent potential applications of AT.

For the person with autism spectrum disorder or other disabilities, their ability to participate in these settings and activities can be impacted by differences in sensory input, movement, cognition and learning, language and communication, or social skills. Some of the AT resources above

contain checklists that can help the team to focus on identifying the person's abilities in that context as well as their disability-related challenges (Reed 2009).

What barriers exist, and what is the impact on the person's participation in the task? Using information that was collected about important contexts and about the person, the team can begin to record the specific challenges that were observed. This information will inform more clearly the purpose and important features of the AT device. Inaccurate identification of the need will make it much less likely that the AT device will be helpful, so this is a key step in the process.

Before moving ahead to thinking about new AT solutions, it is useful to ask find out what strategies and tools that have been tried for this purpose, and what were the results? Being able to reflect on what has been tried and how well it worked will help narrow the scope of the search. Are there features of previous efforts that were beneficial? What other AT options include these features and might be considered? Collecting this type of information can save time and help generate more focused solutions.

A careful process of looking at the context, identifying challenges and contributing factors, and considering prior AT experiences will form a good foundation for identifying AT solutions. What AT tools or strategies might be useful in overcoming the barriers? As part of making that decision, the team should consider the full range of AT options that are available, from the simplest environmental adaptation to a basic tool to a complex computer-based device. Reed (2009) suggests that teams look at a range of sources to learn about options, including books, catalogs, websites, or actual hardware or software. Here is where it is important to have as part of the team at least one person who has some knowledge about relevant assistive technology (Reed 2009) to help evaluate the findings. Different options of AT to meet different needs are presented in the next section.

Based on the collected information, what would be the best idea to try next? What is the plan for implementation of the identified AT solutions? This is the point in the process where the specific device and services are selected. The clear

determination of the target tasks, the assessment of the person's abilities and challenges in that context, and consideration of prior efforts will prepare the assessment team to make informed decisions and thoughtful recommendations for next steps.

Once a decision has been made about what AT to try, a plan for monitoring the trial should be identified. How will training be provided? How and when will the AT be used? What are the indicators of success? What might suggest that the device is not meeting the identified need? Again, the online AT resources are excellent references for suggestions of questions to ask (WATI 2009b; Zabala 2005d; OCALI 2013). Monitoring the final steps of the process is as important as the other steps in ensuring proper implementation and also documentation of benefits and deficiencies.

Even with a good assessment process, it still may be necessary to conduct trials of multiple tools before a solution is identified (Reed 2009). The team may have already created a list of ideas from which to draw their next AT support. Additional trials should follow the same process of planning and documentation until a successful match is made.

The evaluation process defined the context of the need and the necessary features of the device. The step that involves a discussion of potential AT solutions requires an awareness of the continuum of options available for the identified need. The sections below are organized according to broad areas of need: sensory; seating, positioning, mobility, and transportation; reading, writing and computer; cognition and learning; and communication. A brief description of the skills or functions included in that section is followed by list of examples of AT for those purposes. More general names of different types of supports are used as opposed to naming of specific devices, hardware, software, or materials that would be quickly outdated. The topic of communication is covered in detail following the other areas.

AT options related to vision (e.g., cortical vision, visual acuity) include large-print books, Braille, digital books, screen readers, magnification aids, and optical aids.

AT options related to hearing (e.g., hearing acuity, auditory processing, auditory sensitivity) include hearing aids, speech processors, FM systems, alerting systems, captioning, and noise-cancelling headphones.

AT options related to seating, positioning, mobility, and transportation include manual and power wheelchairs, walker, cane, adapted table, stander, seat cushion, adapted chair, positioning wedges, grab bar, wheelchair van, wheelchair lift, and specialized car seat.

AT options for reading, writing, and computer interface include audiobook, E-book or electronic book, screen reader, alternate keyboard, on-screen keyboard, keyguard, joystick, alternate mouse, stylus, voice commands, speech to text application, word prediction applications, eye gaze technology, electronic switch, adapted pen/pencil, and portable electronic device.

AT options for activities of daily living and environmental control (operation of electronics such as lights, phone) include adaptive switches, adapted utensils, specialized handles and grips, switches, alternate keyboards, computers, remote controls, voice command speakers, and portable electronics.

AT to support cognition and learning, such as attention, memory, information processing, knowledge representation and organization, problem-solving, language, and learning (Cook and Polgar 2008), prioritizing, planning, organizing, self-monitoring, and working memory (Temple 2013) includes electronic and nonelectronic materials such as timers, watches, alarms, calendars, reminders, audio recorders, schedules, task lists, sticky notes, graphic organizers, and work systems.

Assistive technology that specifically addresses the needs associated with impairments in speech and communication is called augmentative and alternative communication or AAC. Augmentative communication (AAC) tools and interventions are typically used to supplement a person's existing communication abilities, including any natural speech, rather than replacing it. The purpose of AAC, according to

Light, McNaughton, and Caron (2019), is to “(a) enhance language learning, (b) facilitate social interaction, (c) improve literacy skills, (d) increase participation in society, and (e) teach partner interaction strategies” (p. 26).

No-tech or unaided communication supports use a person’s own body or the environment with no requirement for equipment. Examples include speaking, pointing, gestures, facial expressions, and manual signing. The strengths of unaided methods are that they do not require preparation or management of materials and they are always available and cannot be lost, broken, or damaged and do not cost anything. When used in a context that has information to support a person’s message, gestures, vocalizations, and facial expressions can be very effective forms of communication.

Low-tech communication systems include nonelectronic and paper-based materials. Communication boards, communication books, and paper communication displays are all examples of low-tech supports. The benefits of low-tech supports are that they are typically inexpensive, lightweight, portable, and easily customized. Individuals who use high-tech communication supports often have a low-tech version, created by printing a copy of the displays to use in situations when the device is unavailable or impractical.

High-tech communication aids are often called “speech-generating devices” or SGDs. Because they are computer-based, high-tech SGDs offer many options for how messages can be organized, displayed, and generated. The type of display used in high-tech devices is called a “dynamic display,” where the message targets displayed on the device will change based on the user’s selection. Most high-tech SGDs allow the user to determine the number of cells, or targets, that are displayed on the screen. Some devices will allow the user to create their own cell size and configuration, while others offer a specific set of page layout options. Many devices come with page sets where the display, messages, representations (symbols), and behaviors (response) have already been programmed. By selecting from a set of preprogrammed displays, the person using the device can make necessary edits to individualize their communication support.

When using a keyboard display, as the user types, the letters and words are displayed in a message window or screen that is usually above the keyboard. The message is then spoken by the device. When the device speaks what a user has typed, it is using a form of technology called “text to speech,” which refers to the process of converting the text entered by the user into spoken output.

Until recently, high-tech dynamic display devices were the least available and most expensive type of communication support. With the increase in the use of portable electronics in the general population, the availability of these devices for individuals requiring AAC has also increased. Software applications that support communication have been developed for commercially available electronic devices and can easily be added to mobile devices such as smartphones and tablets (e.g., iPhones, iPads, android phones, and tablets). McNaughton and Light (2013) noted positive contributions of these options included “increased awareness and social acceptance of AAC in the mainstream, greater consumer empowerment in accessing AAC solutions. . .” (p. 107).

With the rapid development of new applications and changes in operating system features, a list of specific communication apps would not be a very relevant resource for long. Instead, the work on mobile media devices (e.g., tablets, phones) by Caron and Shane (2014) outlines the app features that were most desirable for individuals with ASD: purpose; output (speech produced); speech settings; representation (symbols), display (layout, design), and feedback (visual, auditory, tactile); rate enhancement (prediction), access, and motor; and app interface (social). This might be a more useful reference when considering AAC devices.

Future Directions

In their entry on mobile technology, McNaughton and Light (2013) identify evidence-based practices in the field of AAC that are critical to the implementation of any AAC device: proper

assessment of the individual and communicative contexts; device selection and customization based on assessment; focused intervention to increase competency; and training and support of partners.

The concept of universal design has the potential to reduce the need to use assistive technology or individual adaptations. Applying the principles of universal design increases accessibility for all and decreases the need for specialized products for individuals.

Australia and Autism

Lawrence Bartak¹ and Katrina Williams²

¹Faculty of Education, Monash University, Clayton, VIC, Australia

²Developmental Medicine, University of Melbourne, The Royal Children's Hospital and Murdoch Childrens Research Institute, Parkville, VIC, Australia

Historical Background

Australia has a land area about 80 % the size of the USA, China, Europe, and Canada, and 30 times the size of the UK. The total population of Australia is 23 million, with most inhabitants living in several large cities, each with a population of between one and four million. There is a federal system of government, as well as six states and two territories, each with its own state legislature and service systems for health, education, community services, and law. Further, each city or municipal area has a local council and

responsibility for services that impact on people with disability. There are thus three levels of government all with involvement in services of various kinds, quite apart from a range of private foundations, organizations, and corporations which also provide service.

The history of autism in Australia follows that in the USA and the UK, beginning with the pioneering work of Kanner in the USA (Kanner 1943). However, specific interest in autism within Australia, apart from individual clinical work, did not emerge until the 1960s. At this time, significant research findings were beginning to emerge from studies in the UK and USA, and trends in child and adolescent psychology and psychiatry in Australia largely followed developments in these countries. Initially most research and clinical interest was in children in early school year (Bettelheim 1967; DeMeyer et al. 1972; Bartak et al. 1975), usually male, with full scale IQ under 70, with quite severe features of autism and with parents who appeared emotionally stressed. Many clinical programs were focused on the involvement of parents in the development of their child's autism. This was partly because autism was still embedded in psychiatry, and child psychiatric programs in Australia had tended to follow a psychodynamic orientation in the absence of much in the way of objective research on causes of behavioral problems generally. Input from other health professionals from the 1950s to the 1980s would often be limited to neurological opinion to exclude underlying medical conditions. The work of Bettelheim (1967) more specifically in the area of autism within a psychodynamic framework also influenced programs in Australia at this time. However, from the 1960s, new approaches, taking into account behavioral criteria for autistic disorder and intellectual ability, were beginning in Australia, following developments overseas, including the work of Rutter and Schopler (1987), Rimland (1964), DeMeyer et al. (1972), and Ornitz and Ritvo (1968) in the USA and Bartak et al. (1975), Hermelin and O'Connor (1970), and Frith (1989) in the UK.

From the 1980s, in line with other changes in the way services were provided to children (see below), Australia has adopted objective

diagnostic criteria as they have been developed and is looking with interest at the new Diagnostic and Statistical Manual-5 criteria for autism from the American Psychiatric Association (2013).

Diagnosis

As mentioned above, diagnosis of autism was done predominantly by psychologists and psychiatrists in Australia until the 1980s. The service context is important here in thinking about the changes that have occurred over time and the current situation. In Australia, the federal government funds health professionals, including doctors, allied health professionals, and psychologists through Medicare funding, to work in private health-care settings which are run as businesses. In 2008, the federal government launched a funding program called “Helping Children with Autism” (HCWA) that provided funding for diagnosis and assessment of children suspected as having autism, using Medicare billing. The HCWA funding also included intervention funding (see below). The states and territories provide funding for public health-care facilities, including the salaries of health-care professionals. Each state and territory can take and has taken a different, and often changing, approach to the service type and location that they will fund for diagnosis and assessment of developmental problems, including autism. Some diagnostic services are based in hospitals and others in community settings. Consistent features across states and territories have been (1) the emergence of multidisciplinary teams based in publicly funded services, from the 1960s but not widespread until the 1980s for the diagnosis and assessment of children with developmental problems, including autism, usually including a pediatrician (less commonly a child psychiatrist), speech pathologist, and psychologist, but with varying composition between states and territories and between regions within states and territories and no given per capita rationale for geographic location; (2) increasing numbers of pediatricians, speech pathologists, and psychologists working in private settings, in isolation but providing parts of the assessment required for a diagnosis of autism; and (3) greater, but not consistent between

services or clinicians, use of standardized assessment instruments (e.g., Autism Diagnostic Observation Schedule (ADOS) (Lord et al. 2001), Ehlers and Gillberg’s High Functioning Autism Syndrome Screening Questionnaire (ASSQ) (1999), the Autism Diagnostic Interview-Revised (ADI-R) (Rutter et al. 2003), or the Diagnostic Interview for Social and Communication Disorders (DISCO) (Wing et al. 2002)). In Western Australia, an active group of clinicians has developed a standard assessment model which has formed the basis of a multidisciplinary diagnostic and assessment procedure. This procedure has not yet been taken up throughout Australia. Consistent with other high-income countries, Australia has seen a trend toward earlier diagnosis of autism, such that it is now common to see children as young as 2 years of age, and sometimes less than two, presenting with concerns. Children with relatively good language skills are sometimes still not being seen by diagnostic teams until 8–12 years of age.

In parallel with other high-income countries, milder cases are also being diagnosed in Australia. The term autism spectrum disorder had high uptake in Australia by the early 2000s. That conceptualization combined with the use of DSM-IV’s diagnostic category pervasive developmental disorder-not otherwise specified (PDD-NOS) and the acceptance of PDD-NOS as sufficient for service entry saw an increasing number of children with fewer diagnostic features and of lower severity level being labeled.

Early Intervention

Australia has followed the USA, Canada, and the UK in embracing early intervention for children with developmental disorders, including autism. Publicly funded early intervention services developed in Australia during the 1960s. Autism associations also began in Australia in the 1960s, and in that role were some of the earliest “early intervention” providers. Traditionally state governments have provided early intervention for children with substantial developmental problems, based on functional ability and needs rather than diagnosis. The HCWA funding of 2008 transformed the early intervention landscape in

Australia, with families receiving some dedicated federal funding for early intervention services and with one early intervention-enriched child care facility being established in every Australian state. The HCWA funding package provides funding for early intervention for children from diagnosis up to their seventh birthday (however, they must be registered by their sixth birthday), with five being the age of school entry for most children in Australia. An essential and increasing feature of these programs has been to provide support and education for parents so that they can supplement the program activities with structured activities at home.

Education

In 1984, the State of Victoria conducted a review of educational services for disabled children. Prior to this, Victoria and other Australian states had a long history of provision of specialized educational settings for children with various disabilities. Some special schools catered for children with IQ under 70, others for children with sensory or motor difficulties. Schools for children with severe intellectual disability were run by the State Health department as were a number of large long-stay residential institutions, some of which had as many as 900 residents many of whom had been there since early childhood for periods of many years. Children with autism had often been thought to be ineducable and tended to end up in small Health Department schools or the larger residential training centers. The review resulted in radical findings and recommended total inclusion in normal schools for all children with a disability. The small schools for children with severe disability were to be transferred to the State Education Department, and it was expected that all specialist schools would be gradually phased out and closed as all children with a disability would eventually be enrolled in local community public or private schools providing general educational facilities. Where a school had more than six children with special needs, the State Education Department would provide resources to employ a special education teacher and classroom aides. Similar changes have occurred elsewhere in Australia. However, in

many regular schools, aides have often been left to work on their own with children with a disability with insufficient specialist guidance. In addition, closure of special schools has not continued. As a result, while many children with autism go to regular schools, a significant number continue to attend specialist schools which were originally set up for children with intellectual disability and have not been geared to the specific needs of children with autism. Outcomes for children with autism in all of these schools have tended to depend upon the quality of individual teachers and in regular schools, upon the degree of support of school principals. In addition, starting in NSW and Victoria in the 1970s, special schools for children with autism were set up with financial support by parents and private charitable foundations. This followed a similar pattern to what had occurred in the USA, UK, and other parts of the world. In Australia, State Educational Authorities have come to provide some degree of financial and administrative support to such schools in most states.

Adult Years

Over time state autism associations and service providers have recognized at least to some extent that children do not grow out of autism but rather grow with it and become adults with autism. One consequence has been the development of social skills programs that are relevant to the development of both casual and more permanent and intimate social relationships. Some of these include sexual and other health topics as well as the development of basic interpersonal communication skills. As an example, one very successful program developed in Victoria was a "Train the Trainer" program. This was an established course already taught at a technical and further education college which qualified people to become adult education trainers. It was modified to focus specifically on autism. Successful graduates were trained to be public speakers and trainers in the field of autism and could run single sessions or short courses for members of the general public to learn about autism. Twenty adults with autistic disorder were recruited to take the course. Much

of the course involved group project activity as well as extensive class discussion. To some degree of surprise amongst both staff and the class members themselves, participants enjoyed the group activities, and ultimately, 17 of the 20 completed the course and obtained graduate certificates as trainers.

Autism Associations

All states in Australia have autism support associations. These were mostly set up by parents of children with autism when there were few facilities and little governmental support, beginning in the 1960s. In most states, the association has at least one specialist school or class for children with autism and also provides services for children and adults with autism as well as provides information for members of the public, advocacy for the autism community, and parental support services.

Legal Issues, Mandates for Service

While there is no legislation specifically directed to people with autism, Australia has for many years had disability relevant legislation federally as well as in all states and territories. In general, most of this was enacted from 1993 following the United Nations Declaration on the Rights of Disabled Persons. In general, legislation either makes discrimination illegal or makes legal provision for supply of services to people with disability. In 2013, the Federal Government announced a National Disability Insurance Scheme (NDIS) to be developed in cooperation with state governments, to provide financial support to people with disability. This is being modeled on the federal scheme for financial support of people with autism and insurance schemes for those left with a disability following an accident.

Overview of Current Treatments and Centers

Today, each state and territory has their own systems for assessment and diagnosis of autism. In

some states, these systems still reside in mental health services, while in others, they are embedded in child health or disability services. Diagnostic practices within these services vary within and between states. A parallel private system for diagnosis and assessment, as described above, continues to operate, and assessment procedures vary between individual clinicians. In response to a need for quality and consistency, as well as recognition of the need for quality and consistency for other service providers, standards and a scheme for certification have been developed. In this scheme schools, clinics and individual practitioners may become certified as skilled practitioners or service providers in the field of autism. This system is similar to the British accreditation scheme for schools and centers in the UK but includes certification of individual practitioners and services for adults as well as of children's services, as in the UK. The Australian system was developed through the local state autism association in Victoria but is supported by the federal peak body for autism in Australia, the Australian Advisory Board on Autism Spectrum Disorders.

Early intervention services continue to be offered by state and federal governments and often operate as parallel services. Many autism associations also provide early intervention services for children and their parents/carers and educational services, either on a fee for service basis or supported by federal or state funding.

This has been identified as a problem by government, professionals, and consumers, and it is hoped that the new National Disability Insurance Scheme will streamline and improve coordination of care for early intervention.

The issue of *inclusion* continues. In some countries other than Australia (e.g., Britain), there are schools that cater specifically for children with autism and some of these extend to full secondary education. Children attending such schools might then have 12 years of school education with only others with autism as fellow students. In Australia, there are a number of special schools for children with autism. However, these are generally at primary level. Few children with autism would stay in an exclusively autism setting to school leaving age of 17–18. Inclusion

in regular schools has generally been actively promoted in Australia. However, the issue remains as to which setting is more effective for children with autism and few controlled studies have been carried out. Those that have been carried out, including the early studies (Bartak and Rutter 1973), have shown clear support for structured educational methods whatever the overall setting.

Awareness and consideration of the needs of adults with autism continues to develop gradually in Australia. This has been referred to already in connection with social skills programs. However, it has become apparent that a much wider range of services than those provided for children is necessary for adults. These will include work preparation and further education, health education and services, counseling and psychiatric services, aged care, housing and independent living options, leisure and recreational training, transport options and training, and forensic and judicial training and orientation.

Social Justice and Forensic Issues

Although there are few studies either in Australia or elsewhere (Bartak 2011; Cashin and Newman 2009; Newman and Ghaziuddin 2008; Mouridsen 2012), it is apparent that a number of adults with autism may be charged with a variety of offenses. In many instances, the offense will have occurred inadvertently and essentially through a lack of comprehension both on the part of the person with autism and through misunderstanding of autistic behavior by police and judicial staff. While the limited evidence suggests that people with autism spectrum disorders are not more likely to offend than others, they are overrepresented in the justice system. In part this may be owing to failure by family members and staff of community agencies (such as schools or medical facilities) to recognize autism in the respective individual. He or she may then inadvertently break the law for one or other of the above reasons. Provision in this area requires better training of police and judicial staff to increase their understanding of autism, and this is starting to occur in

Australia through joint seminars and other training programs with staff from autism associations, university departments, and members of police and justice departments.

Overview of Research Directions

Until recently, Australia had no systems in place or funding models to connect autism researchers beyond informal email networks. Over the last 5 years, the Australasian Society for Autism Research (ASfAR) has been established and now has over 180 members. This year the federal government funded an application for the formation of a Cooperative Research Center (CRC) for living with autism spectrum disorder. The federal government will provide over \$30 million for 8 years, with additional cash and in-kind contributions from participants and partners exceeding \$60 million. The CRC will support an “across the life-span” program of research. In parallel with other high-income countries, Australian scientists, researchers, and professionals with important skill sets for research in autism (e.g., geneticists, information technology experts, bioengineers, ethicists, and lawyers) have been forming transdisciplinary and intersectoral partnerships with autism experts to advance our knowledge of autism in a way that should lead to improved care and outcomes for those affected. Many universities have acknowledged the importance of autism and related disorders by establishing Chairs in autism and developmental medicine, or similar, and Research Institutes have developed relevant research group hubs. Increasingly, autism associations and the Australian autism peak body are linking directly with researchers.

Description

The Australian Scale for Asperger's Syndrome (ASAS) is a rating scale that aims to assist in the identification of children likely to be at risk of the condition. The scale is based on formal diagnostic criteria, research literature on associated conditions and features, and extensive clinical experience of the authors (Garnett and Attwood 1998). While acknowledging the core sets of criteria developed by organizations, viz., American Psychiatric Association (APA) and the World Health Organization (DSM-IV and ICD-10, respectively), they adopted

the clinically derived diagnostic criteria of Gillberg and Gillberg. Attwood viewed these as “clear, concise and comprehensive” (Attwood 1998, p. 23). The ASAS has not been updated to align with the *Diagnostic and Statistical Manual of Mental Disorders* 5th ed. (DSM-5) (APA 2013) in which Asperger's disorder has been subsumed under the umbrella diagnosis autism spectrum disorder (ASD).

The rating scale is designed to be completed by parents, teachers, or other professionals who know the child. It is comprised of six sections, A–F, and covers behaviors and abilities consistent with a primary-school-age child with the former diagnosis of Asperger's syndrome. These include social and emotional issues, communication skills, cognitive skills, specific interests, movement skills, and a range of other characteristics such as sensory sensitivities, age of language development, and facial tics or twitches.

The scale consists of 24 questions, each with an example of the behavior or skill being determined. Responses are scored on a Likert scale from 0 to 6, with 0 indicating rarely and 6 frequently. Within this scale, 0 is deemed the usual level expected of a child of that age.

The final section (F) consists of a further 10 features or behaviors which the respondent completes as appropriate by ticking the box.

While no specific cutoff is noted, the authors suggest that when the majority of the questions are answered in the affirmative with scores between 2 and 6, a referral for full diagnostic assessment may be indicated. High scores do not, by definition, imply the condition. Full clinical assessment, if this were to be undertaken, would enable further examination of the six core areas rated in the scale.

The authors revised the scale for use with children and adolescents aged 5–18 years (ASAS-R, unpublished Ph.D. thesis, 2007). They advised general adherence to the interpretation of scores as per the original measure. No psychometric data are available at this time. Further work has focused on developing a measure that provides an autism symptomatology profile that in turn may be useful in clinical settings for targeting and measuring intervention impact (Garnett et al. 2013).

Historical Background

The ASAS was originally developed by Garnett as part of a master's thesis in 1993. The scale was further developed by Garnett and Attwood and presented at a conference in Australia in 1998. Only one other scale existed *specific* to the higher functioning end of the spectrum, viz., the Autism Spectrum Screening Questionnaire (ASSQ) developed by Ehlers and Gillberg in Sweden in 1993.

Owing to limited knowledge about Asperger's syndrome among professionals at this time, coupled with the sometimes subtle presentation of features, many children were not being identified as warranting referral to specialist assessment services. Developing screening measures was one way to assist in the identification of possible features and abilities consistent with the condition in order to make appropriate onward referrals. While screening measures, such as the ASAS, were overinclusive, they could facilitate the process whereby possible cases were not missed.

In the first instance, the ASAS was developed for use with primary school children. Garnett and Attwood (2006) revised the original scale and adapted it for use with 5- to 18-year-olds (ASAS-R). The ASAS-R was effectively a new measure of core *dimensions* of Asperger's syndrome. Garnett was especially interested in the association of Asperger/autism symptomatology (AAS) with the psychological health of children and adolescents who had an autism spectrum condition (Garnett 2007). She also sought to evaluate the association between family and peer relationships with psychological health of this group and the level of AAS in those with a diagnosis. Garnett conducted a validation study, the results of which were presented in an unpublished Ph.D. in 2007.

The ASAS has been translated into German, and this version has been validated on a German sample of 51 children (Melfsen et al. 2005). It has been used to examine sex differences in comorbidity and clinical presentation in a Polish sample of adolescents (Rynkiewicz and Lucka 2018).

Psychometric Data

Limited data exist on the psychometric properties of the original measure (Thabtah and Peebles 2019). Table 1 gives the areas evaluated by the ASAS.

In the original study (Garnett, unpublished master's thesis, 1993), ASAS ratings were provided for 60 children and adolescents (3–19 years). Each group consisted of 20 children: (1) diagnosed with AS, (2) clinical group with mixed diagnosis, and (3) typically developing controls. In addition, participants were assessed for level of receptive language.

Multivariate analysis of covariance (MANCOVA) was then conducted for each area score by diagnosis with the receptive language score as the covariate. The nonclinical and AS groups were found to be statistically significantly different in each area to <0.0001.

Discriminant function analysis revealed that the ASAS accurately predicted membership of the groups: 90% for AS, 65% for the mixed clinical group, and 100% for the control group.

No further data were available on test-retest reliability, internal consistency, or discriminant validity of the scale. Small sample sizes and no formal testing as a screening instrument were raised as weaknesses in the scale.

The ASAS was translated into German, and the scale was validated in a study by Melfsen et al. (2005). Mothers of children who were inpatients at a local psychiatric hospital were asked to participate. Three groups of children were rated on the ASAS (German version), viz., AS group (18), referred for assessment but not

diagnosed (18), and a group with mixed psychiatric conditions (15).

Melfsen et al. (2005) report ANOVA results which indicate that the scale successfully differentiated between the three groups. Further stepwise discriminant analysis indicated that group membership was accurately predicted (60.78%). On the basis of these findings, the authors concluded that the ASAS was a useful screening instrument for children with Asperger's syndrome.

The authors have conducted reliability and validity studies on the most recent version of the ASAS, but these are not yet available. Furthermore, these data effectively relate to a *different* measure with a *different purpose*. The proposed revised measure aimed to assess five dimensions of AS to provide information on severity in each dimension and would therefore be helpful to assist in guiding treatment postdiagnosis (Garnett, personal communication, 2011).

Since the initial development of the ASAS, there has been a significant increase in screening and diagnostic tools. Garnett et al. (2013) focused on developing a tool that would provide a profile of individual symptomatology of ASD, that is, The Australian Scale for Autism Spectrum Conditions (ASASC). The authors conducted preliminary psychometric evaluation of the measure and confirmed that the 5-subscale measure mapped reasonably well onto to the two domains of ASD in the DSM-5. While the measure did not aim to serve as a screening tool, the authors reported positive indications that the ASASC may have benefits of identifying autism in addition to the core purpose of (i) identifying an autism profile, including strengths and difficulties to target in intervention, and (ii) providing indicators of change during and following intervention. The authors suggest further replication and validation studies.

Clinical Uses

As per the current range of screening measures for children, adolescents, and adults, the ASAS continues to serve the clinical purpose of identifying

Australian Scale for Asperger's Syndrome, Table 1 Areas of behaviors and skills consistent with Asperger's syndrome (Attwood 1998)

Social and emotional abilities	Other characteristics
Communication skills	Sensory
Cognitive skills	Flapping/rocking
Specific interests	High pain threshold
Movement skills	Delayed speech
	Unusual facial expressions/tics

those children and adolescents who are most at risk of having an autism spectrum condition. It is not evident from the authors whether the ASAS has been replaced by the ASASC.

Not unlike *diagnostic* instruments, screening instruments may not identify those who appear to have more subtle difficulties and differences, such as girls, and those of very significant cognitive abilities. In addition, perhaps in a high-risk family, where others may be affected more significantly, the identified child's features or behaviors are not registered as severe, hence not deemed necessary to assess further.

While the ASAS was one of the earliest attempts at screening for Asperger's syndrome in children, an increasing range of screening tools is now available to identify possible ASD. These cover various age ranges, and while some, like the ASAS, may be completed by laypersons, others are clinician-rated scales. Nonetheless, in clinical practice, these are not infrequently employed alongside other measures, hence providing a wealth of information from a range of sources, that is, clinicians, parents, and teachers. With the shift to ASD as the umbrella diagnostic category, there has been an increase in tools that evaluate autistic profiles such as females versus males (e.g., GQ-ASQ).

- Autism Spectrum Quotient (AQ-child)
- Checklist for Autism in Toddlers (18–24 months)
- Child Behavior Checklist (36–71 months)
- Childhood Autism Spectrum Test (4–11 years)
- Developmental Behavior Checklist – Early Screen (20–51 months)
- Gilliam Autism Rating Scale Third Edition (36–71 months)
- Modified Checklist for Autism in Toddlers (17–48 months)
- Screening Tool for Autism in Toddlers (24–35 months)
- Social Communication Questionnaire (48 months; mental age > 24 months)

While a small validation study in Germany (Melfsen et al. 2005) has confirmed the ASAS's ability to differentiate between three clinical

groups, viz., children with a known diagnosis of AS, children referred for suspected AS, and those referred for other psychiatric conditions, little current information is available regarding the scale's current usefulness as a screening measure or how it compares with other screening measures. Furthermore, lack of clear cutoff scores or indication of the meaning of a particular score renders the instrument difficult to interpret in its current form. Since the scale does not require training or qualification and could hence be employed by clinicians and laypersons alike, the lack of clarity about screening scores and their meaning contributes to the difficulties with interpretation. Nonetheless, if employed as a simple guide prior to discussion about full screening and assessment, the brief, structured scale facilitates an initial evaluation of the child's behavior and presentation within clear areas consistent with the autism spectrum.

The ASAS has undergone significant revisions, and it would appear that the purpose of the various versions is necessarily different. The ASAS has *not* been replaced by the ASAS-R, and the former still serves as a screening instrument (Garnett, personal communication, 2011).

Garnett has suggested the potential value of the ASAS-R in providing directions for intervention. When used in conjunction with additional data regarding family cohesion and peer victimization, this may assist in selecting areas for treatment. However, she notes the need for further research to establish the tool's sensitivity to clinical change. The ASASC appears to be fulfill this objective.

Autistic

Definition

The term “autism” (or autistic) has had several uses in psychiatry. Originally introduced by Bleuler to describe self-centered thinking in schizophrenia, he modified the term from the Greek word for self. In the 1930s, the first child psychiatrist, Leo Kanner, became aware of a group of children who had unusual patterns of social engagement and learning. He published his first 11 cases in 1943 using the term “early

infantile autism” to emphasize the apparent congenital lack of social engagement which he believed to be one of the two cardinal features of the disorder (the other being insistence on sameness/resistance to change). Although children with features suggestive of autism had been described for centuries (likely including some feral children like Victor the Wild Boy in France), Kanner was the first to describe the syndrome in detail. Interestingly, independent of Kanner’s work, the Austrian medical student Hans Asperger also used the term in his description of a similar condition in highly verbal but socially isolated and eccentric boys.

Although he initially emphasized the unique aspects of the condition, Kanner’s use of the term also suggested a link to schizophrenia given Bleuler’s earlier use of the term, and indeed until 1980 autism was not recognized as an official diagnosis and children with what today would be said to have autism were instead thought to exhibit a form of childhood schizophrenia. By the late 1970s, this state of affairs changes with recognition of the uniqueness of autism (based on clinical features, onset, family history, neurobiological, and genetic findings) led to its explicit recognition as a category of disorder distinct from schizophrenia.

As time has gone on, the condition now known as Autism Spectrum Disorder has evolved in terms of the stringency of the specific diagnostic concept. At the same time a growing body of both behavioral and genetic work suggests that a broader spectrum of the condition clearly exists likely paralleling the awareness of the diverse number of genes that might contribute to the pathogenesis of the condition.

As work on the social neuroscience of autism has increased, the insight of Kanner in using this term to characterize the condition is increasingly appreciated.

Autism Acceptance and Mental Health

Eilidh Cage

Department of Psychology, University of Stirling, Stirling, Scotland, UK

Definition

Acceptance, appreciation, and acknowledgement of autism as part of a person, both in terms of self-acceptance and how accepting other people are. Perceiving a lack of acceptance could relate to poorer mental health for autistic people.

Historical Background

Historically, the narratives around autism often focus on deficits, perhaps stemming from its first conception where Kanner (1943) described “autistic disturbances” and autistic behaviors are

often pathologized as not “normal” (Milton and Bracher 2013). For many years, autism research has been dominated by biological studies (e.g., genetic and neuroscientific research) and treatment or intervention studies (Pellicano et al. 2014) which likely proliferates the narrative that autism is something which should be cured rather than accepted. In more recent years, the ethics behind such autism research has been questioned (Pellicano and Stears 2011), with growing acknowledgment of the need for a shift in the narrative (Gillespie-Lynch et al. 2017) as well as increased participatory research whereby autistic people are meaningfully included in autism research (Fletcher-Watson et al. 2019).

The shift in narrative and the idea of accepting autism as an integral part of a person is related to the concept of neurodiversity, a term first credited to Judy Singer (1999). The neurodiversity movement celebrates diverse autistic thinking, views autism as part of identity, and is opposed to autism “cures” (Kapp et al. 2013) while still acknowledging the difficulties autistic people face and not minimizing disability (Den Houting 2019). This movement relates to the social model of disability (Shakespeare 2006) which proposes that disability can be the result of incompatibility with the environment and society. For example, one could argue that society’s lack of acceptance of autism could be a significant factor in the underemployment of autistic people rather than autistic characteristics preventing employment. Generally, these approaches highlight that autism is not perceived to be currently accepted within society.

This poor acceptance could relate to the mental health of autistic people. Autism itself is not a mental health condition, but autistic individuals experience high rates of mental health difficulties, for example, depression (Stewart et al. 2006), anxiety (Gillott and Standen 2007), social anxiety (Maddox and White 2015), and suicidal behavior and ideation (Cassidy et al. 2014). Prevalence estimates vary widely, for example, between 28% and 86% of autistic people have been suggested to experience diagnosable mental health conditions (Howlin and Magiati 2017). Despite this variability, it is asserted that autistic people experience mental health difficulties at

a higher rate than non-autistic people (Lai et al. 2019). These mental health difficulties make everyday life more challenging for autistic people and likely contribute to poorer quality of life (Robertson 2009).

The reasons why mental health conditions are highly prevalent in autism are not well understood and may depend on the specific mental health condition. Further, it is unlikely that the high prevalence is caused by one single factor, but a myriad of both internal and external contributing factors which enhance the risk of poor mental health. Internal factors might include genetic predispositions or certain cognitive biases. For example, in anxiety in autism, a mode of thinking known as “intolerance of uncertainty” has been found to link to increasing anxiety (Boulter et al. 2014). External factors might include aspects of the world dependent on other people, such as lack of social support, or the sensory environment – for example, hypersensitivity to the sensory environment has been noted to play a role in heightening anxiety in autism (Green and Ben-Sasson 2010). More recently, the role of autism acceptance has been examined as an external contributing factor to poor mental health in autism.

Current Knowledge

Autistic adults tend to perceive that within society, they are not accepted for being autistic, and a lack of perceived acceptance from others relates to higher symptoms of depression and stress (Cage et al. 2018). Robertson et al. (2018) found that autistic adults experiencing high rates of anxiety discussed how acceptance from others helped mitigate some of their anxiety symptoms, but they continued to fear the judgment of others. Participants in Cage et al.’s (2018) study described how they were often misunderstood or even completely dismissed by others and they used tactics to hide their autistic characteristics and therefore “pass” within society unnoticed as an autistic person. These tactics have been conceptualized as “camouflaging” (Hull et al. 2017), and the use of camouflaging has been argued as a means of protecting the self against

nonacceptance and discrimination from others (Cage and Troxell-Whitman 2019). Further, high rates of camouflaging have been found to relate to poorer mental health (Hull et al. 2019). Trying to fit into a predominantly non-autistic and non-accepting society is thus a mentally exhausting endeavor.

Autism acceptance can also be measured by examining antonymous concepts such as autism-related stigma. Stigma is the attachment of negative attitudes and stereotypes toward a group of people, and the discreditation and discrimination of the group (Goffman 1990), in this case autistic people. Botha and Frost (2018) argue that autistic people are a stigmatized minority group and are subject to “minority stress” – in other words, the stress associated with being labeled as part of a discriminated minority. Botha and Frost (2018) supported this minority stress model by finding that experiences of discrimination, concealment of autistic status, and internalized stigma related to poorer mental health in a sample of autistic adults. Together, this research suggests that perceived lack of acceptance in the form of stigma can have a negative relationship with mental health.

Other research has examined the self-acceptance of autism, which can also be thought of in terms of autistic identity. The terminology used to describe autism can be classified as either person-first (person with autism) or identity-first (autistic person). Kenny et al. (2016) found in a sample of British autistic participants that the majority preferred identity-first terminology. The participants described how person-first terminology positioned autism as something separate to the self, when in fact autism colors every element of how the individual processes the world and was therefore an inseparable part of the person. Similarly, Kapp et al. (2013) found that stronger identification with an autistic identity was associated with viewing autism more positively and as something that should not be “cured.” Further, Kapp et al. (2013) noted that preference for identity-first language did not mean that these participants lessened the difficulties associated with autism. It is important to bear in mind that acceptance does not mean ignoring or reducing the everyday difficulties associated with autism,

but rather to understand and acknowledge these, alongside autistic strengths (Den Houting 2019; Kapp et al. 2013).

Research has attempted to examine the links between self-acceptance, in terms of identifying with an autistic identity, and mental health. Cooper et al. (2017) measured autistic social identity (i.e., identifying as part of the autistic community) and mental health. They found that autistic identification could protect against anxiety and depression through promoting higher personal self-esteem (the value placed on one’s self) and collective self-esteem (the value placed on autistic people as a group). In this way, identifying with the autistic community could protect against mental health problems through taking pride in being part of this community and potentially drawing on support from other autistic people. In a review and synthesis of qualitative literature, Kim (2019) noted links between positive autistic self-identity and greater self-determination (an attitude toward being in control of one’s own life), which they suggest could link to better quality of life and ability to manage stress. Although the above research suggests that acceptance of being autistic links to better mental health outcomes, it can be challenging to achieve self-acceptance, especially considering the discrimination and stigma experienced by autistic people.

As such, researchers have not only examined autistic people’s perceptions of acceptance but have tried to survey non-autistic people’s attitudes toward autism, to measure the levels of acceptance within society. Knowledge about autism in Western populations is thought to be relatively good (Tipton and Blacher 2014) although some misunderstandings and misconceptions can still occur (Dillenburger et al. 2015) as well as many believing myths about autism (John et al. 2018). Autism-related stigma has also been measured, for example, as “openness” toward autism (Gardiner and Iarocci 2014) or the desire for social distance from autistic people (Gillespie-Lynch et al. 2015), with these studies finding that less stigma is associated with prior experience and contact with autistic people themselves. Notably, non-autistic people can falsely believe that they

are more helpful toward autistic people than they actually are (Heasman and Gillespie 2019), suggesting that non-autistic people likely attempt to provide socially desirable responses that present themselves in a positive light – thus survey measures of stigma are considered with caution.

Experimental research has therefore looked at non-autistic people's acceptance of autism through inventive means which may be less affected by social desirability than survey methods. For example, a growing body of research looks at the "first impressions" of autistic people. First impressions are the rapid judgments made about a person on first interacting with them (Ambady et al. 2000). One approach to test these first impressions is to ask observers to rate people they view in brief video clips. In one of Sasson et al.'s (2017) experiments, it was unknown to the observers that half of the people in the videos were autistic. Sasson et al. (2017) found that more negative judgments of the autistic people were formed, with autistic people rated as more awkward, less likeable, and attractive than non-autistic people, and there was less desire to hang out, talk to, or make friends with the autistic individuals. Interestingly, Sasson and Morrison (2019) found that labeling the video participants as autistic helped to improve first impressions. Further, Morrison et al. (2019) found that personal characteristics of the observers, such as pre-existing stigmatizing attitudes and knowledge about autism, could better explain poor first impressions than the characteristics of the autistic people in the videos. Together, these findings suggest that non-autistic people have negative biases against autism, but with intervention non-autistic people could overcome their difficulties with accepting autistic people.

Future Directions

More research is needed to find means of improving autism acceptance in the non-autistic population. Interventions have been trialled within educational establishments – such as Gillespie-Lynch et al.'s (2015) online training for university

students. Here, the training taught students about a range of different aspects including autistic strengths and difficulties, autism as a spectrum condition, etiology, and neurodiversity. After completing the training, there were improvements in knowledge and reductions in stigma toward autism. These findings are thus promising, with subsequent replications in non-Western countries such as Lebanon (Obeid et al. 2015) and Japan (Someki et al. 2018). Other anti-stigma interventions with school-aged girls have also shown promise in teaching girls about autism, with associated reductions in stigma (Ranson and Byrne 2014). Often research finds that girls and women tend to be more open toward autism (e.g., Cage et al. 2019; Nevill and White 2011); thus future research needs to understand why this is the case and what can be done to improve male's attitudes toward autism. Further, more research is needed on interventions outside of educational settings as well as longitudinal studies to test whether the effects of interventions persist beyond the short term.

Additionally, the difficulties in autistic to non-autistic interactions can be thought of in terms of a "double empathy problem," which can be described as interactional clashing between autistic and non-autistic people, with neither group understanding one another well (Milton et al. 2018). Mitchell et al. (2019) argue that the double empathy problem should be considered in tandem with the mental health difficulties experienced by autistic people. It seems that autistic people expend significant effort to understand and fit in to the predominantly non-autistic world, and this can be mentally and physically exhausting (Cage and Troxell-Whitman 2019). Achieving acceptance may involve reducing the "gap" between autistic and non-autistic perspectives and non-autistics putting in equal effort to understand autistic perspectives. Research on the double empathy problem is in its infancy but shows promise (Milton et al. 2018).

It should also be carefully considered how current practices in education, the media, healthcare and research might be perpetuating stigma. For example, Bottema-Beutel et al. (2018) discuss how social skills training may

implicitly enforce stigma and the necessity of camouflaging, since this training suggests that autistic people need to conform to a non-autistic standard of social communication. Instead, they argue that autistic people need to be able to explore their authentic selves and critically appraise non-autistic social rules, but more research is needed in this area. Furthermore, the narratives perpetuated in the media about autism are also thought to enforce stigma (Holton et al. 2014). Health practitioners too – trained predominantly in terms of a medical or deficit model of autism – need to acknowledge their role in promoting autism acceptance in those just diagnosed as well as in families and caregivers (Nicolaidis 2012). Future research should examine the impact of training, particularly using a social model or neurodiversity approach, on reducing stigma within professionals who encounter autistic people in their work.

Listening to – and including – autistic perspectives within research could be vital in improving autism acceptance. Research which does meaningfully involve autistic people is growing, with several researchers (autistic and non-autistic) developing frameworks and guidelines for this type of research (Chown et al. 2017; Fletcher-Watson et al. 2019). For example, Chown et al. (2017) outline how research should be aligned with the priorities of autistic people themselves, that the social model of disability should be at the research's core and outcomes should center around improving the everyday lives of autistic people. Similarly, Fletcher-Watson et al. (2019) highlight the need for elements such as empathy, authenticity, and respect within autism research. Researchers should consider how these guidelines could be incorporated into their future work and how their research supports the aim of improving autistic people's lives and the inclusion of autistic people in society.

By striving to make the world a more accessible place for autistic people, we may see concurrent improvements in autistic people's mental health. Of course, mental health is affected by numerous factors, and more research is needed to fully understand mental health in autism and appropriate treatments to reduce these difficulties.

Ultimately, autistic people must be accepted for being autistic people, not as camouflaged versions of themselves.

Synonyms

Epilepsy and autism

Introduction

Autism spectrum disorders (ASD) and epilepsy are both clinically heterogeneous entities whose co-occurrence has long been recognized to exist at a frequency that is greater than could be predicted by chance alone. This observation has led to interest in the possibility of shared causal pathways for both disorders and raises the possibility of future novel interventions that could impact the course of both conditions. Further, the co-occurrence of the disorders presents several diagnostic and treatment challenges and controversies. This encyclopedia entry will provide an overview of terminology, epidemiology and etiology, clinical expression, available findings on developmental course, issues in differential diagnosis, and treatment considerations.

Categorization

Terminology

Terms associated with autism include autism spectrum disorder (ASD), high-functioning autism (HFA), pervasive developmental disorders (PDD), and infantile autism. ASD are behaviorally defined disorders, with literature still utilizing these terms despite the presentation of revised diagnostic criteria in the DSM-5. These terms are defined in introductory chapters in this encyclopedia. Key terms associated with epilepsy include seizure disorder and pediatric seizure disorder. A seizure is commonly understood as uncontrolled electrical activity in the brain, which may produce a physical convulsion, minor physical signs, changes in consciousness, thought disturbances, sensory disturbances, or a combination of symptoms. While the terms seizure disorder and epilepsy are generally used interchangeably, epilepsy is more formally defined as having two or more seizures within a set period of time, most often within 3 years, for which there is no other identifiable cause such as mass lesion, head trauma, infection, toxic exposure, or metabolic derangement (Matson and Neal 2009).

Epidemiology

Epidemiology and Etiology

The prevalence of autism in the pediatric population is approximately 14.6 cases per 1,000 children, with a national rate of approximately 1 in 68 cases at age 8 years. Estimated prevalence was significantly higher for boys at about 23.6 per 1,000, than for females at about 5.3 per 1,000 (Christensen et al. 2016). These rates are higher among non-Hispanic white children at about 15.5 per 1,000 than for non-Hispanic black children (13.2 per 1,000) and Hispanic children (10.1 per 1,000); however, it is suspected that these differences in rates are related more to access to care as opposed to true differences in prevalence across racial and ethnic lines (Durkin et al. 2010; Morbidity and Mortality Weekly Report 2012). Further, autistic traits are about 4.5 more commonly seen in males, with a staggering rate of

1 in 42, than for females (1 in 189) (Christensen et al. 2016).

In the general pediatric and adult population, the prevalence of epilepsy is 2–3% (Canitano 2007), with recent estimated lifetime rates of about 10.2 per 1,000 (Russ et al. 2012). The prevalence of having epilepsy and autism as co-occurring, or perhaps comorbid conditions ranges widely from 8% to 30% (Mouridsen et al. 2013; Russ et al. 2012; Spence and Schneider 2009; Tuchman et al. 2010), with children with ASD having a 7- to 10-fold increased odds compared to controls for having epilepsy (Jokiranta et al. 2014; Tuchman et al. 2013). Viscidi et al. (2013) found that the prevalence of epilepsy in children with ASD was about 12–13% for children ages 2–17, with rates rising to about 26% for adolescents age 13 and above. For children with epilepsy, about 30% will eventually have a diagnosis of ASD (Keller et al. 2017), and individuals with epilepsy diagnosed in childhood are at significant risk for later manifestation of ASD (Sundelin et al. 2016). While there does not appear to be a specific form of epilepsy that is present in children with ASD, epilepsy does appear to be present more frequently in individuals with ASD and Intellectual Disability, with the rates increasing with the severity of the Intellectual Disability (Jokiranta et al. 2014). Of significant concern, there also is increased risk for mortality for individuals with ASD and epilepsy, particularly in the presence of an intellectual disability (Woolfenden et al. 2012).

Etiological Mechanisms

The frequency of co-occurrence of these two disorders has led to interest in the possibility of shared etiological mechanisms in seizure disorders and ASD. Proposed theories of shared causality have been related to the deleterious effects of the seizures themselves and associated imbalances between neuronal excitation and inhibition (Stafstrom and Benke 2015), with a particular focus on impaired GABAergic signaling as being a common denominator for co-occurring ASD and epilepsy (Kang and Barnes 2013; Tuchman et al. 2013). Additionally, contemporary mechanistic understandings of several

key neurodevelopmental disorders have led to new theories about the shared role of impaired plasticity during development (Keller et al. 2017).

For example, portions of the temporal lobe of the brain and associated neural pathways are likely to be key brain regions in the complex network that has been described as “the social brain.” The temporal lobe has long been a suspected region of importance because of the relative frequency of temporal lobe epilepsy both among patients with epilepsy with social challenges and among those with ASD and epilepsy. Animal research using mouse models has demonstrated that mice with induced temporal lobe seizures exhibited less social behavior than control mice (Marin et al. 2008). Neuroimaging studies in patients with temporal lobe epilepsy have provided evidence showing damage to other recognized social brain structures in this network, such as the hippocampus (Dager et al. 2007). Further, such studies also have begun to show a linkage between aberrant neural migration over the course of neurodevelopment (Blackmon 2015) and general neurological vulnerability (Gilby and O’Brien 2013) to seizures in individuals with ASD.

Another set of examples wherein a potential shared mechanism for both ASD and seizure disorders has begun to be explored comes from the study of several recognized genetic syndromes that are associated with both autism features and seizures (Keller et al. 2017; Lee et al. 2015). In this regard, fragile X, tuberous sclerosis complex, and Rett’s syndrome all have been proposed as possible models of overlapping causality in ASD and epilepsy/seizures. For example, Rett’s syndrome is a neurodegenerative disorder that affects girls and is currently understood to be caused by mutations in the gene encoding methyl-CpG binding protein 2 (MeCP2). Rett’s syndrome is characterized by regression of verbal skills along with repetitive hand motions that usually begin to occur between 6 and 18 months of age (Brooks-Kayal 2010). Up to 90% of Rett’s syndrome patients develop seizures (Canitano 2007). Tuberous sclerosis has been associated with both epilepsy and autism (Jeste et al. 2016). The prevalence of tuberous sclerosis in the general population is around 1 case per 10,000 to

20,000 (Sherpherd 1999). Around 1% of children with autism will have tuberous sclerosis (Harrison and Bolton 1997), and approximately 80% of patients with tuberous sclerosis will also have seizures (Canitano 2007). With respect to epilepsy, tubers are thought to be foci of epileptic activity, and many of the ASD symptoms have been linked to tubers found in the temporal lobes of the brain (Bolton et al. 2002). Finally, fragile X syndrome is the most common form of inheritable intellectual disability, and frequently manifests with co-occurring autism and seizures. This syndrome is caused by excessive CGG trinucleotide repeats on the X chromosome, methylating either in whole or in part the Fragile X Mental Retardation gene leading to many of the phenotypic features associated with fragile X syndrome (Brooks-Kayal 2010). With approximately one third of individuals with fragile X syndrome showing co-occurring ASD, this syndrome provides a clear single gene disorder for examining not just autism but its related comorbidity.

While exact mechanisms for the behavioral manifestations remain unknown in each of these disorders, there has been an expanding knowledge base relating to presumed causal genetic defect (s) and their downstream molecular effects. Resultant impaired inhibitory/excitatory regulation and impaired neuroplasticity have been proposed as a possible common explanation for seizures and ASD-related behaviors (Brooks-Kayal 2010). Further, a number of other gene mutations have been associated with ASD, Intellectual Disabilities, and epilepsy/seizures including the genes encoding neuroligins, neurexins, arestelles region X-linked (ARX), and neuropilin-2 (Brooks-Kayal 2010).

Clinical Expression and Pathophysiology

There are a number of ways that the co-occurrence of seizures and ASD can be examined in terms of clinical expression and variables associated with seizure pathophysiology. These include: type of seizures, seizure location, epilepsy syndromes, age of seizure onset, level of intellectual functioning, and developmental course.

Type of Seizures

There are several classification schemas for seizure types and epilepsy. The most commonly used classification is based on the broad categories of generalized seizure onset versus focal onset, each with subcategorizations based on various clinical features and origin of seizure activity. Further, there are numerous recognized epilepsy syndromes. Seizure types in individuals with ASD are highly variable, and multiple seizure types in the same individual are not uncommon. It is important to note, though, that the prevalence of particular seizure types among those with both disorders does not seem to differ significantly from the distribution of seizure types in epilepsy patients in general (Sternberg 2003).

Seizure Location

There is a suggestion that seizure location may point to a relationship with autistic features or autism. In epilepsy in which the seizure activity manifests from the frontal lobe, behavioral changes may include irritability, altered mood, subtle changes in alertness, associated attention dysregulation, and cognitive rigidity features often associated with ASD (Fohlen et al. 2004). Seizures originating in the temporal lobe may be associated with autistic features or autism (Hamiwka and Wirrell 2009) in that the individual may present with affective blunting, odd or impaired language functions, including impairments in core language functions or pragmatics, and poor recognition of faces.

Epilepsy Syndromes

The relationship between ASD and seizures also can be understood by considering the presence of an epilepsy syndrome. There are numerous epilepsy syndromes, and those that are believed to contribute to progressive disturbance in cerebral function may be termed “epileptic encephalopathies.” These disorders begin early in life and are often associated with regression of cognitive, language, and other neurodevelopmental functions. Many children with these disorders may present with features of ASD or they may in fact meet diagnostic criteria for an ASD (Nabbout and Dulac 2003; Nabbout and Dulac 2008). Among these syndromes, infantile spasms (IS), Landau-

Kleffner syndrome (LKS), and epilepsy with continuous spike-waves during slow-wave sleep (CSWS) are most strongly associated with ASD symptomology (Ballaban-Gil and Tuchman 2000).

In IS, the association with ASD may as high as 35%, and this risk seems to increase in the presence of a severe intellectual disability, structural brain lesions, and ongoing epileptiform activity in frontal brain regions (Kayaalp et al. 2007; Saemundsen et al. 2007, 2008). LKS and CSWS have overlapping symptoms in relationship to seizure presentation, and both manifest features that overlap with ASD symptoms. The failure or regression of language development in these disorders often leads to confusion with autistic regression that is reported in children with and without underlying seizure disorders (Canitano 2007).

Age of Seizure Onset

The relationship between ASD and seizures/epilepsy can also be investigated by considering the age of seizure onset. It has been theorized that epilepsy with a late onset during adolescence is brought on by the hormonal fluctuations associated with puberty (Gillberg 1991). One study of children with autism showed that seizure activity peaks between 3 and 10 years of age (Matson and Neal 2009). Other studies, however, have suggested that epilepsy has two peaks in children with autism: one during infancy and another during adolescence (Volkmar and Nelson 1990). The peak during infancy may correlate with the peak of seizure activity that is seen in children with epilepsy without autism, while the second peak during adolescence may be unique to children with autism (Nomura et al. 2010). Recent data have challenged this bimodal distribution, suggesting that the primary peak occurs by 6 years of age (Jokiranta et al. 2014).

Intellectual Functioning

The range of the overall level of intellectual functioning in individuals with ASD is quite large and variable; however, it has been well established that in populations of children with epilepsy, the risk of autism or autistic features is increased among those with the lowest intellectual functioning (Hamiwka and Wirrell 2009; Jokiranta et al. 2014). Among populations of children with ASD,

those with severe intellectual disability, severe receptive language deficits and motor dysfunction (i.e., those with more severe autism symptoms) have the highest risk of epilepsy (El Achkar and Spence 2015; Mulligan and Trauner 2014; Tuchman et al. 2009); and, conversely, children with ASD and epilepsy manifest more cognitive and neuropsychiatric difficulties than those without epilepsy (Viscidi et al. 2014; Weber and Gadow 2017).

Developmental Course

When considered independently, the developmental course, severity, and outcomes of individuals with ASD and epilepsy are highly variable and dependent on numerous factors. To date, there are scant empirical data related to the moderating or mediating effects of epilepsy and ASD on one another in relation to developmental course and outcomes. In general, children with comorbid or co-occurring ASD and seizures/epilepsy have lower IQ, lower adaptive behavior, more emotional problems, and have more frequent use of psychiatric medications (Matson and Neal 2009). Also, a higher rate of seizure activity has been linked to decreased intellectual functioning (Jokiranta et al. 2014; Matson and Neal 2009) but is unclear how medications or other factors (e.g., other neurological factors) may be contributing to this suspected association. Additionally, the presence of temporal lobe seizures has been described as a poor prognostic indicator in relation to social adaptation among individuals with ASD and seizure disorders (Matson and Neal 2009). As noted above, the notion that children with comorbid ASD and seizure disorders have more pronounced social impairment when compared to children with ASD who do not have seizures has been proposed, but this issue is only beginning to be evaluated (Tuchman 2013).

Evaluation and Differential Diagnosis

Issues in Differential Diagnosis

Early diagnosis and treatment of both epilepsy and autism are crucial in order to maximize development and quality of life (Tuchman et al. 2010). Early identification and treatment allow for

the optimal usage of all therapies and resources available. The potential co-occurrence of these disorders does raise several important issues in differential diagnosis. For example, the mainstay of evaluation in seizure disorders is the electroencephalogram (EEG), but a seizure evaluation also can include metabolic and genetic components. It is important to note that abnormal EEG activity can be seen in 7–28% of children with autism, but without any other symptoms of epilepsy (Youroukos 2007). On the other hand, high-functioning individuals with autism may be missed when presenting for epilepsy treatment (Matsuo et al. 2010). The association between autism and seizures has led the Committee on Children with Disabilities of the American Academy of Pediatrics to recommend prolonged sleep-deprived EEG in children with ASD showing developmental regression or in those where there is a high suspicion of subclinical seizures (American Academy of Pediatrics 2001). Due to the current dearth of empirical knowledge about subclinical epileptiform activity and its treatment, universal screening via EEG for all children with ASD has not yet been recommended as a standard of care (Johnson and Myers 2007), but its routine use has been suggested (Swatzyna et al. 2017).

Another important area of concern relates to the convergence of sleep problems in the populations of children with ASD and epilepsy/seizures. Sleep difficulties are common among individuals with neurologic disorders in general as well as in those with ASD and seizure disorders (Malow 2004). Screening for sleep problems and formal sleep evaluations (based on clinical need) are often important for individuals presenting with comorbid ASD and epilepsy (Accardo and Malow 2017). Sleep disorders have significant implications for behavioral functioning and quality of life beyond challenges associated with the underlying disorder (Clarke et al. 2005), such as creating daytime sleepiness, increased irritability, less efficient cognitive functioning (potentially in addition to cognitive impairment), and decreased seizure threshold. Further, sleep studies in children with ASD and sleep problems in rare instances may elucidate a previously unrecognized seizure disorder related to sleep (Accardo and Malow 2017; Malow 2004).

Treatment Considerations

Early recognition of ASD and co-occurring epilepsy is important in that it is hoped that developmental outcomes can be improved via early treatment. Medication is a first-line treatment in children with epilepsy. The chief goal here is to eliminate (or lessen) all seizure activity while minimizing medication-related side effects such as behavioral problems or weight gain. In autism, psychosocial and behavioral interventions are commonly used as first-line interventions for behavioral symptoms. In autism, medication treatment is used as an adjunctive therapy to lessen symptoms of inattention, hyperactivity, repetitive behaviors, impulsivity, irritability, and aggression (Tuchman et al. 2010).

Antiepileptic medications (AEDs) are the mainstay of treatment in epilepsy. Several AEDs are used commonly in general psychiatric practice due to beneficial psychotropic properties, most notably in mood stabilization and the mitigation of aggression. Examples include valproic acid, carbamazepine, lamotrigine, and levetiracetam. While a full discussion of this class of medication is beyond the scope of this chapter, the aforementioned AEDs have been evaluated in the ASD population with and without epilepsy in several case series or small open-label trials. At present, AEDs seemed to have had equivocal results in terms of benefit with irritability, aggression, or behaviors associated with the core features of autism such as repetitive behaviors (Hirota et al. 2014; Tuchman et al. 2010), and concerns always are present for the medications to create affective blunting and/or to negatively impact cognitive and social capabilities. Formal evaluation via large randomized clinical trials in the ASD population with seizures is lacking and will be an important future step in guiding the care of this population (Tuchman et al. 2010).

Epileptic encephalopathies associated with ASD, such as infantile spasms (IS) or Landau-Kleffner syndrome (LKS), are treated early and aggressively with AEDs, adrenocorticotropin hormone (ACTH), steroids, the ketogenic diet, or surgery. The main focus of these interventions is to improve seizure control. Outcomes of these

practices as they relate to mitigation or prevention of ASD features are unknown (Crumrine 2002; Kosso et al. 2005; Trevathan 2002; Wheless 2004).

The treatment of epileptiform activity on EEG, without the presence of clinical seizures, is an area of considerable debate. This debate is most relevant among those with ASD showing cognitive regression, but without a clear epilepsy syndrome or epileptic encephalopathy. Approximately 30% of children with ASD present autistic regression, which is understood as a loss of verbal and nonverbal communication skills between approximately 12 and 24 months of age. The relationship between regression and epileptiform activity noted in this subgroup has been postulated, but remains unclear, and treatment recommendations for this subgroup remain without a clear evidence base (Baird et al. 2006; Venkateswaran and Shevell 2008).

New information about shared genetic and molecular causal pathways may provide new insights about the management of children with epilepsy and autism. For example, in fragile X syndrome, mouse models have provided evidence that FMRP dysfunction may lead to behavioral and cognitive deficits as well as seizure formation (Brooks-Kayal 2010; Penagarikano et al. 2007). A key target in this dysregulation may be the metabotropic glutamate receptor (MgluR). Modulation of MgluR in mouse models has provided promising results in terms of behavior, cognition, and seizure formation (Brooks-Kayal 2010). Several molecules that modulate the function of this receptor are currently in various phases of development. Their role in epilepsy treatment and treatment of any ASD feature remains to be seen, but it is clear that much is to be learned from conditions where ASD and epilepsy coexist (Brooks-Kayal 2010).

Conclusion

This encyclopedia entry provided an overview of the interesting association between autism and seizures disorders. This is an intriguing area for clinical inquiry, but it is also an area ripe for

scientific investigation. With the prevalence of seizure disorders in the general population being approximately 2–3%, the rate of seizures in the population of individuals with autism is arguably as high as 22 times as much, with about one third experiencing at least one seizure by adolescence. With the recently documented prevalence of autism in the population, this combines to create a significantly large number of individuals with comorbid ASD and seizures. As a subgroup of individuals with ASD, however, this area has only begun to receive scientific scrutiny. Increased understanding of the type of seizures, identifiable neurological contributors, other associated conditions, and developmental course all should contribute to improved seizure management. Key to this understanding is early, comprehensive evaluation and associated differential diagnosis. Also, recognizing that at least one-third will manifest a seizure by adolescence implicates the need for routine and thorough developmental surveillance for seizure manifestations by an interdisciplinary group of trained professionals (Eom et al. 2014). Ultimately, coordinated multimodal treatment approaches will be critical to maintaining a good quality of life for individuals with ASD and comorbid seizure disorders. Although treatment of epilepsy is a medical necessity, it typically will not be enough to address the additional symptoms related to ASD and related social and cognitive functioning (Tuchman 2013).
